D2892 describes the procedure for the distillation of stabilized crude petroleum to a final cut temperature of 400 °C AET (atmospheric equivalent temperature). The test method employs a fractionating column having an efficiency of 14 to 18 theoretical plates operated at a reflux ratio of 5 : 1. Performance criteria for the necessary equipment is specified. Some typical examples of acceptable apparatus are presented in schematic form. This test method offers a compromise between efficiency and time in order to facilitate the comparison of distillation data between laboratories. It is commonly referred to as ''standard'' TBP distillation. Although only indirectly related to most gasoline volatility standards, the standard contains a wealth of information. TBP values have the property of being blendable in linear fashion without a severe loss of accuracy. D86 and other ASTM assay methods are not so readily predictable for multiple blended cuts TBP values can be reasonably converted to and from D86, D1160, and D2887 values via the API Technical Databook Method 3A1.1.

The test method gives details of procedures for the production of a liquefied gas, distillate fractions and residuum of standardized quality on which analytical data can be obtained, and the determination of yields of the above fractions by both mass and volume. From the above information a graph of temperature versus mass-percent distilled can be produced. This distillation curve corresponds to a laboratory technique which is defined at 15/5 (15 theoretical plate column, 5 : 1 reflux ratio) or TBP.

This test method can also be applied to any petroleum mixture except LPGs, very light naphthas, and fractions having IBPs above 400 °C.

D2892 contains the following Annexes:

- Annex A1 – Test Method for the Determination of the Efficiency of a Distillation Column.
- Annex A2 – Test Method for the Determination of the Dynamic Holdup of a Distillation Column
- Annex A3 – Test Method for the Determination of the Heat Loss in a Distillation Column (Static Conditions),
- Annex A4 – Test Method for the Verification of Temperature Sensor Location
- Annex A5 – Test Method for Determination of the Temperature Response Time
- Annex A6 – Practice for the Calibration of Sensors
- Annex A7 – Test Method for the Verification of Reflux Dividing Valves
- Annex A8 – Test Method for Dehydration of a Sample of Wet Crude Oil
- Annex A9 – Conversion of Observed Vapor Temperature to atmospheric equivalent temperature (AET)
- Annex A10 – Practice for Performance Check.

7.3.6 D5307 Determination of Boiling Range Distribution of Crude Petroleum by Gas Chromatography

This test method covers the determination of the boiling range distribution of water-free crude petroleum through 538 °C (1000 °F). Material boiling above 538 °C is reported as residue. D-5307 is applicable to whole crude samples that can be solubilized in a solvent to permit sampling by means of a microsyringe.

7.3.7 D1078-95 Distillation Range of Volatile Organic Liquids

This test method covers the determination of the distillation range of liquids boiling between 30 and 350 °C, which are chemically stable during the distillation process. D-1078 is applicable to organic liquids such as hydrocarbons, oxygenated compounds, chemical intermediates, and blends thereof. Typically this has been replaced by the D-86 standard.

7.3.8 Nonstandard Distillation Methods – High-temperature Extended Simulated Distillation

A few simulated distillation GC vendors have equipment to extend the range of the GC/simdist standards above by high-temperature simulated distillation (HTSD). This relatively new method which extends ASTM D-2887 determination of the boiling range distribution of hydrocarbons to a FBP of about 1400 °F (760 °C). The use of capillary GC column and stationary phase technology advances,

together with either programmed temperature vaporization (PTV) or on-column injection techniques, provides adequate separation of from C_5 to C_{20} normal paraffins allowing the characterization of petroleum products from about 97 to 1380 °F (36–750 °C).

7.4 *V/L* Methodology

7.4.1 D2533 Vapor–Liquid Ratio of Spark-ignition Engine Fuels

This test method covers a procedure for measuring the volume of vapor formed at standard atmospheric pressure from a given volume of gasoline. The ratio of these volumes is expressed as the vapor–liquid (V/L) ratio of the gasoline at the temperature of the test.

Dry glycerol can be used as the containing liquid for nonoxygenated fuels. Mercury can be used as the containing liquid with both oxygenated and nonoxygenated fuels. Because oxygenates in fuels may be partially soluble in glycerol, gasoline–oxygenate blends must be tested using mercury as the containing fluid. Test Method D-4815 can be used to determine the presence of oxygenates in fuels first.

7.4.2 D5188 Vapor–Liquid Ratio Temperature Determination of Fuels (Evacuated Chamber Method)

D-5188 covers the determination of the temperature at which the vapor formed from a selected volume of volatile petroleum product saturated with air at 0–1 °C (32–34 °F) produces a pressure of one atmosphere in an evacuated chamber of fixed volume. It is applicable to samples for which the determined temperature is between 36 and 80 °C (97 and 176 °F) and the vapor–liquid ratio is between 8 to 1 and 75 to 1.

When the vapor–liquid ratio is 20:1, the result is intended to be comparable to the results determined by Test Method D-2533. This test method may also be applicable at pressures other than one atmosphere, but the stated precision may not apply. It is, however, applicable to both gasoline and gasoline–oxygenate blends.

Other standards of possible use in distillation and V/L analysis of regulated fuel components are:

- ASTM D-216 – Distillation of Natural Gasoline, Standard Method for. This is now supplanted mostly by D-86 on stabilized naphthas from NGL recovery plants
- ASTM-E1405 – Laboratory Glass Distillation Flasks, Standard Specification for
- ISO-918 – Volatile Organic Liquids for Industrial Use – Determination of Distillation Characteristic
- ASTM D-1093 – Acidity of Hydrocarbon Liquids and Their Distillation Residues, Standard Test Method for
- ISO 3405 Petroleum products – Determination of Distillation Characteristics
- ISO/DIS 3924 Petroleum products – Determination of Boiling Range Distribution – Gas Chromatography Method (Revision of ISO 3924: 1977)
- ISO/DIS 6616 Petroleum products – Determination of Distillation Characteristics at Reduced Pressures.

7.5 Measurement of Reid Vapor Pressure – Gasoline Products

7.5.1 D323 Vapor Pressure of Petroleum Products (Reid Method)

This is the original RVP test standard. This test method covers four procedures for the determination of vapor pressure of gasoline, volatile crude oil, and other volatile petroleum products. Procedure A is applicable to gasoline and other petroleum products with a vapor pressure of less than 180 kPa (26 psi). Procedure B may also be applicable to these other materials, but only gasoline was included in the interlaboratory test program to determine the precision of this test method. Neither procedure is applicable to liquefied petroleum gases or fuels containing oxygenated compounds other than MTBE or alcohols. Procedure C is for materials with a vapor pressure of greater than 180 kPa (26 psi) and Procedure D for aviation gasoline with a vapor pressure of approximately 50 kPa (7 psi).

Because the external atmospheric pressure is counteracted by the atmospheric pressure initially present in the vapor chamber, the RVP is an absolute pressure at 37.8 °C (100 °F) in kilopascals (pounds-force per square inch). The RVP differs from the true vapor pressure of the sample because of some small sample vaporization and the presence of water vapor and air in the confined space. It is *not* suitable for use with oxygenated fuels. For determination of the vapor pressure of gasoline–oxygenate blends, refer to Test Method D4953.

7.5.2 D4953 Vapor Pressure of Gasoline and Gasoline–Oxygenate Blends (Dry Method)

This test method, a modification of test Method D323 (Reid method), provides two procedures to determine the vapor pressure of gasoline and gasoline–oxygenate blends. Again, because the external atmospheric pressure is counteracted by the atmospheric pressure initially present in the air chamber, this vapor pressure is an absolute pressure at 37.8 °C (100 °F) in kilopascals (pounds-force per square inch). This vapor pressure differs from the true vapor pressure of the sample because of some small vaporization of the sample and air in the confined space.

D4953 is applicable to gasolines and gasoline–oxygenate blends with a vapor pressure range from 35 to 100 kPa (5–15 psi). Vapor pressure of gasoline or gasoline–oxygenate blends below 35 kPa (5 psi) or greater than 100 kPa (15 psi) can be determined with D4953, but the precision and bias as described in section 10 of the standard do not apply. For materials with a vapor pressure greater than 100 kPa (15 psi), use the 0 to 200 kPa (0–30 psi) gage as specified in the Annex of Test Method D323.

7.5.3 D5190 Vapor Pressure of Petroleum Products (Automatic Method)

D5190 covers the determination of the total pressure of air-containing volatile petroleum products. It is suitable for testing samples with bps above 0 °C (32 °F) that exert a vapor pressure between 7 and 172 kPa (1 and 25 psi) at 37.8 °C (100 °F) at a vapor-to-liquid ratio of 4 : 1. This test method is suitable for testing gasoline samples that contain oxygenates. No account is taken of dissolved water in the sample.

This test method is suitable for the calculation of a DVPE by means of a correlation equation (see section 6.5.2.2). The calculated DVPE very closely approximates the dry vapor pressure that would be obtained on the same material when tested in accordance with test Method D4953.

7.5.4 D5191 Vapor Pressure of Petroleum Products (Mini Method)

D-5191 covers the use of automated vapor pressure instruments to determine the total vapor pressure exerted in vacuum by air-containing volatile liquid petroleum products. This test method is suitable for testing samples with bps above 0 °C (32 °F) that exert a vapor pressure between 7 and 130 kPa (1.0 and 18.6 psi) at 37.8 °C (100 °F) at a vapor-to-liquid ratio of 4 : 1. Measurements are made on liquid sample sizes in the range of 1–10 mL. No account is taken of dissolved water in the sample. Samples can also be tested at other vapor-to-liquid ratios, temperatures, and pressures, but the precision and bias statements need not apply.

D-5191 is suitable for calculation of the DVPE of gasoline and gasoline–oxygenate blends by means of a linear correlation equation. The calculated DVPE very closely approximates the dry vapor pressure that would be obtained on the same material when tested by test Method D-4953.

7.5.5 D5482 Vapor Pressure of Petroleum Products (Mini Method–Atmospheric)

This test method provides a procedure for the determination of total vapor pressure of petroleum products using automatic vapor pressure instruments. The test method is suitable for testing samples with bps above 0 °C (32 °F) that exert a vapor pressure between 7 and 110 kPa (1.0 and 16 psi) at 37.8 °C (100 °F) at a vapor-to-liquid ratio of 4 : 1. D5482 is applicable to gasolines containing oxygenates. No account is taken of dissolved water in the sample.

Because the external atmospheric pressure does not influence the resultant vapor pressure, this vapor pressure is an absolute pressure at 37.8 °C (100 °F) in kPa (psi). This vapor pressure differs from the true vapor pressure of the sample because of some small vaporization of the sample and dissolved air into the air of the confined space.

The D-5482 test is a modification of Test Method D5191 (mini method) where the test chamber is at atmospheric pressure prior to sample injection. It covers the use of automated vapor pressure instruments that perform measurements on liquid sample sizes in the range from 1 to 10 mL. D5482 is also suitable for the determination of the Test Method D4953 DVPE of gasoline and gasoline–oxygenate blends by means of a correlating equation.

7.5.6 D2889 Calculation of True Vapor Pressures of Petroleum Distillate Fuels

This test method describes the calculation of true vapor pressures of petroleum distillate fuels for which data may be obtained in accordance with Test Method D-86 without reaching a decomposition point prior to obtaining 90 volume% distilled. D-2889 may be used to calculate vapor pressures at temperatures between the 0% equilibrium flash temperature and the critical temperature of the fuel. Provisions are included for obtaining a calculated critical temperature for fuels for which it is not known.

The method is not reliable for distillate fuels having a boiling range of less than 100 °F (38 °C) between the ASTM Test Method D-86 10 and 90 volume% distilled temperatures.

Other applicable standards for RVP analysis are found in:

- ISO 3007 Petroleum Products – Determination of Vapor Pressure – Reid method

7.6 Detection and Measurement of Aromatics – Gasoline/Avgas Cuts

7.6.1 D5580-95 Determination of Benzene, Toluene, Ethylbenzene, p/m-*Xylene,* o-*Xylene, C_9 and Heavier Aromatics, and Total Aromatics in Finished Gasoline by Gas Chromatography*

D5580 covers the determination of benzene, toluene, ethylbenzene, the xylenes, C_9 and heavier aromatics, and total aromatics in finished motor gasoline by

GC. The aromatic hydrocarbons are separated without interferences from other hydrocarbons in finished gasoline. Nonaromatic hydrocarbons that have a bp greater than *n*-dodecane may cause interference with the determination of the C_9 and heavier aromatics. For the C_8 aromatics, *o*-xylene and *m*-xylene co-elute, while ethylbenzene and xylene are separated. The C_9 and heavier aromatics are determined as a single group.

This test method covers the following concentration ranges, in liquid volume%, for the preceding aromatics: benzene, 0.1–5%; toluene, 1–15%; individual C_8 aromatics, 0.5–10%; total C_9 and heavier aromatics, 5–30%, and total aromatics, 10–80%. Results are reported to the nearest 0.01% by either mass or by liquid volume.

Many of the common alcohols and ethers that are added to gasoline to reduce carbon monoxide emissions and increase octane, do not interfere with the analysis. Ethers such as MTBE, ETBE, TAME, and diisopropyl ether (DIPE) have been found to elute from the precolumn with the nonaromatic hydrocarbons to vent. Other oxygenates, including methanol and ethanol, elute before benzene and the aromatic hydrocarbons. 1-Methylcyclopentene has also been found to elute from the precolumn to vent and does not interfere with benzene.

7.6.2 D5769 Determination of Benzene, Toluene, and Total Aromatics in Finished Gasolines by Gas Chromatography/Mass Spectrometry

This test method covers the determination of benzene, toluene, and total aromatics in finished motor gasoline, including RFG containing oxygenated blending components, by GC/MS. It is applicable to the following concentration ranges, in liquid volume%, for the following aromatics: benzene 0.1–3%; toluene 1–15%; and total (C_6–C_{12}) aromatics 10–40%. D-5769 has not been tested by ASTM for gasoline samples containing a concentration of uncalibrated C_{10}–C_{12} aromatic compounds greater than approximately 3 volume%. Also, the test method has not been tested by ASTM for individual hydrocarbon process streams in a refinery, such as reformates, fluid catalytic cracked naphthas, and so on, used in blending of gasolines.

Results are reported to the nearest 0.01% for benzene and 0.1% for the other aromatics by either mass or liquid volume.

7.6.3 D4420-94 Determination of Aromatics in Finished Gasoline by Gas Chromatography

The D4420 test method provides for the determination of benzene, toluene, C_8, C_9 and heavier aromatics, and total aromatics in finished motor gasoline. It is also applicable to gasoline blending components. For analysis of gasolines for benzene and toluene, solely, test Method D-3606 is appropriate.

D-4420 is applicable to the following concentration ranges, in liquid volume percent, for the individual aromatics listed above: benzene, 0.1–5; toluene, 1–20; C, 3–25; C and heavier, 5–30, and total aromatics, 10–80. Results are reported to the nearest 0.1% by liquid volume.

D4420 is slightly more accurate than D-5580, but it has not been determined whether this test method is applicable to gasoline containing oxygenates.

7.6.4 D3257-e1 Aromatics in Mineral Spirits by Gas Chromatography

These test methods cover the determination of ethylbenzene and total eight-carbon (C_8) and heavier aromatics in the concentration range from 0.1 to 30% in mineral spirits having a distillation range from 149 to 210 °C (300–410 °F) as determined by Test Method D86. The procedures permit the identification and calculation of concentrations of aromatic components to 0.1 volume%.

Oxygenated compounds, if present, may interfere and cause erroneous results. Such oxygenated compounds are not normally present in mineral spirits. Two test methods are covered as follows:

- Test Method A, measurement of ethylbenzene content, C plus higher aromatics (except ethylbenzene), and total aromatics by means of a single GC analysis.
- Test Method B, measurement of ethylbenzene content by means of a rapid GC analysis.

7.6.5 D5292 Aromatic Carbon Contents of Hydrocarbon Oils by High Resolution Nuclear Magnetic Resonance Spectroscopy

D-5292 covers the determination of the aromatic hydrogen content (Procedures A and B) and aromatic carbon content (Procedure C) of hydrocarbon oils using high-resolution NMR spectrometers. Applicable samples include kerosines, gas oils, mineral oils, lubricating oils, coal liquids, and other distillates that are completely soluble in chloroform and carbon tetrachloride at ambient temperature. For pulse Fourier transform spectrometers, the detection limit is typically 0.1 mol% aromatic hydrogen atoms and 0.5 mol% aromatic carbon atoms. For continuous wave (CW) spectrometers, which are suitable for measuring aromatic hydrogen contents only, the detection limit is considerably higher and typically 0.5 mol% aromatic hydrogen atoms.

The reported units are mole percent aromatic hydrogen atoms and mole percent aromatic carbon atoms. This test method is not applicable to samples containing more than 1 mass% olefinic or phenolic compounds, and neither does it cover the determination of the percentage mass of aromatic compounds in oils, since NMR signals from both saturated hydrocarbons and aliphatic substituents

on RA compounds appear in the same chemical shift region. For the determination of mass or volume percent aromatics in hydrocarbon oils, chromatographic, or mass spectrometry methods can be used.

7.6.6 D5776 Bromine Index of Aromatic Hydrocarbons by Electrometric Titration

This test method determines the amount of bromine-reactive material in aromatic hydrocarbons and is thus a measure of trace amounts of unsaturates in these materials. It is applicable to materials having bromine indexes below 500.

The D-5776 standard is applicable to aromatic hydrocarbons containing no more than trace amounts of olefins and that are substantially free from material lighter than isobutane and have a distillation EP under 288 °C (550 °F)

7.6.7 D2789 Hydrocarbon Types in Low-olefinic Gasoline by Mass Spectrometry

This test method discusses the determination by mass spectrometry of the total paraffins, monocycloparaffins, dicycloparaffins, alkylbenzenes, indans or tetralins or both, and naphthalenes in gasoline which have an olefin content of less than 3 volume% and a 95% distillation point of less than 210 °C (411 °F) as determined in accordance with Test Method D-86. Olefins are determined by Test Method D-1319, or by Test Method D-875. It has not been determined if D2789 is sufficiently applicable to gasolines containing oxygenated compounds (for example, alcohols and ethers).

7.7 Detection and Measurement of Aromatics – Turbine and Diesel Fuels

7.7.1 D2549 Separation of Representative Aromatics and Nonaromatics Fractions of High-boiling Oils by Elution Chromatography

D-2549 methodology covers the separation and determination of representative aromatics and nonaromatics fractions from hydrocarbon mixtures that boil between 232 and 538 °C (450 and 1000 °F). Alternative procedures are provided for the separation of 2 g or 10 g of hydrocarbon mixture. Some components may not be eluted from the chromatographic column for some types of sample under the conditions used in this method. It is not applicable to gasoline range cuts.

Test Method D-2007 is an alternative method of separating high-boiling oils into polar compounds, aromatics, and saturates fractions.

7.7.2 D2425 Hydrocarbon Types in Middle Distillates by Mass Spectrometry

This test method covers an analytical scheme using the mass spectrometer to determine the hydrocarbon types present in virgin middle distillates 204–343 °C (400–650 °F) boiling range, 5–95 volume% as determined by Method D86. Samples with an average carbon number value of paraffins between C_{12} and C_{16} and containing paraffins from C_{10} and C_{18} can be analyzed. Eleven hydrocarbon types are determined. These include paraffins, noncondensed cycloparaffins, condensed dicycloparaffins, condensed tricycloparaffins, alkylbenzenes, indans or tetralins, or both, C_nH_{n-10} (indenes, etc.), naphthalenes, C_nH_{n-14} (acenaphthenes, etc.), C_nH_{n-16} (acenaphthylenes, etc.), and tricyclic aromatics.

7.8 General Ponaffin, Isoponaffin, Aromatic, Naphthene, Olefin Analyses for Aromatics and Other Components

7.8.1 D3238 Calculation of Carbon Distribution and Structural Group Analysis of Petroleum Oils by the n-d-M *Method*

D3238 discusses the calculation of the carbon distribution and ring content of olefin-free petroleum oils from measurements of refractive index, density and molecular weight (*n-d-M*). This test method should not be applied to oils whose compositions are outside the following ranges: in terms of carbon distribution – up to 75% carbon atoms in ring structure; percentage in RAs not larger than 1.5 times the percentage in naphthenic rings; in terms of ring content – one can have up to four rings per molecule, with not more than half of them aromatic. A correction must be applied for oils containing significant quantities of sulfur.

The composition of complex petroleum fractions is often expressed in terms of the proportions of RA, naphthene rings (RN) and paraffin chains (CP) that would comprise a hypothetical mean molecule. Alternatively, the composition may be expressed in terms of a carbon distribution, that is, the percentage of the total number of carbon atoms that are present in RA structures (% CA), naphthene ring structures (% CN) and in CP (% CP).

7.8.2 D5134 Detailed Analysis of Petroleum Naphthas Through n-*Nonane by Capillary Gas Chromatography*

This test method covers the determination of hydrocarbon components of petroleum naphthas. Components eluting after *n*-nonane (bp 150.8 °C) are determined as a single group. Components that are present at the 0.05 mass % level or greater can be determined.

D5134 applies to olefin-free (<2% olefins by liquid volume) liquid hydrocarbon mixtures including virgin naphthas, reformates, and alkylates. Olefin content can be determined by Test Method D1319. The hydrocarbon mixture must have a 98% distillation point of 250 °C or less as determined by Test Method D3710.

7.8.3 D5443 Paraffin, Naphthene, and Aromatic Hydrocarbon-type Analysis in Petroleum Distillates through 200 °C by Multidimensional Gas Chromatography

This test method provides for the determination of paraffins, naphthenes, and aromatics by carbon number in low-olefinic hydrocarbon streams which have FBPs of 200 °C or less. Hydrocarbons with bps greater than 200 °C and less than 270 °C are reported as a single group. Olefins, if present, are hydrogenated and the resultant saturates are included in the paraffin and naphthene distribution. Aromatics boiling at C_9 and above are reported as a single aromatic group.

D5443 was not intended to determine individual components except for benzene and toluene that are the only C_6 and C_7 aromatics, respectively, and cyclopentane, which is the only C_5 naphthene. The lower limit of detection for a single hydrocarbon component or group is 0.05 mass%. This test method is applicable to hydrocarbon mixtures including virgin, catalytically converted, thermally converted, alkylated and blended naphthas.

Some other standards and reference sources for aromatics analyses in hydrocarbon fuels are:

- API-4439 – Exposure Data on C7 and C8 Aromatics During Handling and Production of Motor Gasolines
- ASTM D-2267 – Aromatics in Light Naphthas and Aviation Gasolines by Gas Chromatography, Standard Test
- ASTM D-875 – Calculation of Olefins and Aromatics in Petroleum Distillates from Bromine Number and Acid a″
- ISO 5661: 1983 Petroleum Products – Hydrocarbon Liquids – Determination of Refractive Index
- ISO 3837: 1993 Liquid Petroleum Products – Determination of Hydrocarbon Types – Fluorescent Indicator Adsorption Method
- ISO 2549 – Separation of Representative Aromatics and Nonaromatics Fractions of High Boiling Oils by Elution Chromatography.

7.9 Detection and Measurement of Benzene

7.9.1 D3606 Determination of Benzene and Toluene in Finished Motor and Aviation Gasoline by Gas Chromatography

This test method provides for a primary standard for the determination of benzene and toluene in finished motor and aviation gasolines by GC. As such, the standard mandates calibrations before routine sample preparation and analysis, all of which adds up to a fairly tedious process. Benzene can be determined between the levels of 0.1 and 5 volume% and toluene can be determined between the levels of 2 and 20 volume%. It has not been determined whether D3606 is applicable to gasolines containing oxygenated compounds (for example, alcohols or ethers). Ethanol is known to interfere with the benzene determination and some modifications of the GC column to correct for this are being considered.

7.9.2 D4053 Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy

This test method covers the determination of the percent benzene in full-range gasoline. It is applicable to concentrations from 0.1 to 5 volume%. D-4053 has not been validated for gasolines containing oxygenates.

7.9.3 D4534-e1 Benzene Content of Cyclic Products by Gas Chromatography

This test method covers the determination of the benzene content of specific cyclic hydrocarbon products. Benzene may be determined over a range from 5–300 mg kg^{-1}. The products in which benzene can be determined include cyclohexane, toluene, individual C_8 aromatics, cumene, and styrene.

Some other standards and reference sources for benzene analysis in hydrocarbon fuels are:

- API-DR-111 – Estimation of Incremental Benzene Exposure Associated with Bulk Gasoline Storage
- API-DR-195 – Naturally Occurring Benzene, Toluene and Xylenes in Soils
- API-DR-221 – Removal of Benzene from Refinery Wastewater
- API-4470-1 – Volume 1: Exhaust Benzene Emissions from Late Model Vehicles
- ASTM D-1017 – Benzene and Toluene in 250F and Lighter Petroleum Products by Ultraviolet Spectrophotometer
- ASTM D-4053 – Benzene in Motor and Aviation Gasoline by Infrared Spectroscopy, Standard Test Method for
- ASTM D-4367 – Benzene in Hydrocarbon Solvents by Gas Chromatography, Standard Test Method for
- ASTM D-4534 – Benzene Content of Cyclic Products by Gas Chromatography, Standard Test Method for
- ASTM D-4600 – Determination of Benzene-soluble Particulate Matter in Workplace Atmospheres, Standard
- ASTM D-5580 – Determination of Benzene, Toluene, Ethylbenzene, *p*/*m*-Xylene, *o*-Xylene, C_9 and Heavier Aromatics
- ASTM D-5769 – Determination of Benzene, Toluene, and Total Aromatics in Finished Gasolines by Gas Chromatography.

See also the above section on aromatics and PIANO analysis standards.

7.10 Detection and Measurement of Olefins

Although no specific recommendations for one method over another is promoted (beyond mentioning the regulatory requirements) in most of section 7, an exception must be made here.

Olefins are a priority control constituent for CARB and US EPA Phase II gasolines. The US EPA has proposed that fuel olefins of ozone-forming potential be measured via the FIA analysis procedures outlined in ASTM D-1319. Several sources, including the author, have noted that FIA olefins for high olefins gasoline blend stocks may be far less accurate than alternative means of measurements.

This applies most to unhydroprocessed thermally cracked streams in a refinery. Chiefly these are FCC and coker light cuts that happen to go to the gasoline pool. The FCC gasoline may have as much as 50% olefinic material, the coker as much as 10%. If it is necessary to control the rates of either of these blend stocks into the blend header with a potential olefins constraint, one should exercise caution in the assumed amount of the stock that will meet all criteria based on linear blend values of properties. A safe option would be to assume 10–15% more olefin in the stock than what is reported by FIA analysis, at least until a detailed biasing study is performed with several months of on-line data available.[76]

7.10.1 D1159 Bromine Numbers of Petroleum Distillates and Commercial Aliphatic Olefins by Electrometric Titration

This test method covers the determination of the bromine number of petroleum distillates that are substantially free of material lighter than isobutane and that have 90% distillation points (by Test Method D-86) under 327 °C (626 °F). This test method is generally applicable to gasoline (including leaded, unleaded and oxygenated fuels), kerosine, and distillates in the gas oil range that fall within the following limits: bromine number at 90% distillation point, under 205 °C (400 °F) = 2 and from 205 to 327 °C (400–626 °F) = 10.

The magnitude of the bromine number is an indication of the quantity of bromine-reactive constituents, not an identification of constituents; therefore, its application as a measure of olefinic unsaturation should not be undertaken without the study given in Annex A1 of the standard.

For petroleum hydrocarbon mixtures of bromine number less than 1.0, a more precise measure for bromine-reactive constituents can be obtained by using Test Method D-2710. If the bromine number is less than 0.5, then Test Method D-2710 or the comparable bromine index methods for industrial aromatic hydrocarbons, Test Method D-1492, must be used in accordance with their respective scopes. The practice of using a factor of 1000 to convert bromine number to bromine index is not applicable to these lower values of bromine number.

7.10.2 D1319-a Hydrocarbon Types in Liquid Petroleum Products by Fluorescent Indicator Adsorption

This test method is for determining hydrocarbon types over the concentration ranges from 5–99 volume% aromatics, 0.3–55 volume% olefins, and 1–95 volume% saturates in petroleum fractions that distill below 315 °C, although some reports sharply limit this effective range. D-1319 may apply to concentrations outside these ranges, but the precision has not been determined. Samples containing dark-colored components that interfere in reading the chromatographic bands cannot be analyzed.

This test method is intended for use with full boiling range products. Comparative data have established that the precision statement does not apply to narrow boiling petroleum fractions near the 315 °C limit. Such samples are not eluted properly, and results are erratic.

The precision statement for this test method has been determined with unleaded fuels that do not contain oxygenated blending components. It may or may not apply to automotive gasolines containing lead antiknock mixtures or oxygenated gasoline blending components, or both.

The following oxygenated blending components: methanol, ethanol, MTBE, TAME and ETBE do not interfere with the determination of hydrocarbon types at concentrations normally found in commercial blends. These oxygenated components are not detected, since they elute with the alcohol desorbent. Other oxygenated compounds must be individually verified. When samples containing oxygenated blending components are analyzed, the results must be corrected to a total-sample basis.

7.10.3 D2710-e1 Bromine Index of Petroleum Hydrocarbons by Electrometric Titration

This test method covers the determination of the amount of bromine-reactive material in petroleum hydrocarbons, and is thus a measure of trace amounts of unsaturates in these materials. It is applicable to materials having bromine indexes below 1000.

The D-2710 test method is applicable only to essentially olefin-free hydrocarbons or mixtures that are substantially free from material lighter than isobutane and have a distillation end point (EP) under 288 °C (550 °F). This procedure has been comparatively tested on materials with bromine indexes in the range from 100 to 1000. These materials include petroleum distillates

such as straight-run and hydrocracked naphtha, reformer feed, kerosine, and aviation turbine fuel. Materials with bromine index greater than 1000 should be tested for bromine number using Test Method D-1159/IP 130. Industrial aromatic hydrocarbons should be tested using Test Method D-1492.

Other possible applicable standards for olefins analysis are:

- ASTM D-875 – Calculation of Olefins and Aromatics in Petroleum Distillates from Bromine Number and Acid
- ISO 3837 Liquid Petroleum Products – Determination of Hydrocarbon Types – Fluorescent Indicator Adsorption (FIA) Method
- ISO 3839 Petroleum Products – Determination of Bromine Number of Distillates and Aliphatic Olefins – Electrometric Method

7.11 Detection and Measurement of Sulfur

7.11.1 D1266 Sulfur in Petroleum Products (Lamp Method)

D-1266 covers the determination of total sulfur in liquid petroleum products in concentrations from 0.01 to 0.4 mass% (Note 1). A special sulfate analysis procedure is described in Annex A1 that permits the determination of sulfur in concentrations as low as 5 mg kg^{-1}.

The direct burning procedure (section 9) is applicable to the analysis of such materials as gasoline, kerosine, naphtha, and other liquids that can be burned completely in a wick lamp. The blending procedure (section 10) is applicable to the analysis of gas oils and distillate fuel oils, naphthenic acids, alkyl phenols, high sulfur-content petroleum products, and many other materials that cannot be burned satisfactorily by the direct burning procedure.

Phosphorus compounds normally present in commercial gasoline do not interfere. A correction is given for the small amount of acid resulting from the combustion of the lead antiknock fluids in gasolines. Appreciable concentrations of acid-forming or base-forming elements from other sources interfere when the titration procedure is employed because no correction is provided in these cases.

7.11.2 D2622 Sulfur in Petroleum Products by X-ray Spectrometry

D2622 covers the determination of total sulfur in liquid petroleum products and in solid petroleum products that can be liquefied with moderate heating or dissolved in a suitable organic solvent. The applicable concentration range will vary to some extent with the instrumentation used and the nature of the sample. Optimum conditions will allow the direct determination of sulfur in essentially paraffinic samples at concentrations exceeding 0.0010 mass%.

Methanol containing fuels M-85 and M-100 may be analyzed with an accompanying loss of sensitivity and precision because of the more absorbing matrix caused by the high oxygen content of these fuels. M-85 is 85% methanol–15% gasoline, and M-100 fuel is 100% methanol. Correction factors are applied to achieve these results.

7.11.3 D3227 Mercaptan Sulfur in Gasoline, Kerosine, Aviation Turbine, and Distillate Fuels (Potentiometric Method)

This test method covers the determination of mercaptan in gasolines, kerosines, aviation turbine fuels, and distillate fuels containing from 0.0003 to 0.01 mass% of mercaptan sulfur. Organic sulfur compounds such as sulfides, disulfides, and thiophene do not interfere. Elemental sulfur in amounts less than 0.0005 mass% does not interfere. Hydrogen sulfide will interfere, if not removed.

7.11.4 D4294 Sulfur in Petroleum Products by Energy-dispersive X-ray Fluorescence Spectroscopy

This standard covers the measurement of sulfur in hydrocarbons such as naphthas, distillates, fuel oils, residues, lubricating base oils and nonleaded gasoline. The concentration range is from 0.05 to 5 mass%.

D-4294 applicable tests may involve hazardous materials, operations, and equipment. The standard does not purport to address all of the safety concerns, if any, associated with its use. It is the responsibility of the user of this standard to establish appropriate safety and health practices, and then determine the applicability of regulatory limitations prior to use. For specific precautionary statements, see section 7.

7.11.5 D4952 Qualitative Analysis for Active Sulfur Species in Fuels and Solvents (Doctor Test)

This test method is intended primarily for the detection of mercaptans in motor fuel, kerosine, and similar petroleum products. This test is one of the oldest in the refining industry, but still reasonably accurate.

7.11.6 D5623 Sulfur Compounds in Light Petroleum Liquids by Gas Chromatography and Sulfur-selective Detection

This test method covers the determination of volatile sulfur-containing compounds in light petroleum liquids. It is applicable to distillates, gasoline motor fuels (including

those containing oxygenates) and other petroleum liquids with a FBP of approximately 230 °C (450 °F) or lower at atmospheric pressure. The applicable concentration range will vary to some extent depending on the nature of the sample and the instrumentation used; in most cases, however, the test method is applicable to the determination of individual sulfur species at levels of $0.1-100\,mg\,kg^{-1}$.

D-5623 does not purport to identify all individual sulfur components. Detector response to sulfur is linear and essentially equimolar for all sulfur compounds within the standard's scope (1.1). Both unidentified and known individual compounds can be determined. Many sulfur compounds, for example, hydrogen sulfide and mercaptans, are reactive and their concentration in samples may change during sampling and analysis. Consequently, the total sulfur content of samples is estimated from the sum of the individual compounds determined. The D-5623 test method is not the preferred method for determination of total sulfur if some other less roundabout analysis method is available.

Other possible applicable standards for sulfur analysis are:

- ISO 4260 Petroleum Products and Hydrocarbons – Determination of Sulfur Content – Wickbold Combustion Method
- ISO 8754 Petroleum Products – Determination of Sulfur Content – Energy-dispersive X-ray Fluorescence Method
- ISO/DIS 14596 Petroleum Products – Determination of Sulfur Content – Wavelength-dispersive X-ray Fluorescence Spectrometry
- ISO-6326-3 – Part 3: Determination of Hydrogen Sulfide, Mercaptan Sulfur and Carbonyl Sulfide Sulfur B
- ASTM D-1219 – Fuel, Aviation Turbine, Mercaptan Sulfur in (Color Indicator Method)
- ASTM D-129 – Sulfur in Petroleum Products (General Bomb Method), Standard Test Method for
- ASTM D-1323 – Fuels, Aviation Turbine, Mercaptan Sulfur in, Amperometric and Potentiometric Methods
- ASTM D-2747 – Trace Quantities of Total Sulfur in Volatile Organic Liquids (Oxyhydrogen Combustion Method)
- ASTM D-2785 – Trace Quantities of Total Sulfur (Wickbold & Beckman Combustion Apparatus)
- ASTM D-3246 – Microcoulometry, Standard Test Method for Sulfur in Petroleum Gas by Oxidative SCAQMD-307 Speciated Sulfur Content for Reformulated Gasolines.

7.12 Detection and Measurement of Oxygenates in Fuel

Tests applicable to gasoline are not necessarily applicable to its blends with oxygenates. Consequently, the type of fuel under consideration must first be identified in order to select applicable tests. Standard D-4814 outlines the oxygenate requirements and Test Method D-4815 provides a procedure for determining oxygenate concentration in mass percent. These tests have not yet to withstand the test of time, so always exercise appropriate professional judgment in their use.

7.12.1 D4814-c Automotive Spark-ignition Engine Fuel

Though not really an analysis standard, D-4814 sets the guidelines in establishing requirements of automotive fuels for ground vehicles equipped with spark-ignition engines. It is included here as a reminder to analysts that this is the defining specification for the amounts and types of oxygenates that are required to be in RFG, including such items as seasonality and variations in amounts. It changes often and the latest version should always be used for setting control targets in the blender.

D-4814 describes various characteristics of automotive fuels for use over a wide range of operating conditions. It provides for a variation in the volatility and water tolerance of automotive fuel in accordance with seasonal climatic changes at the locality where the fuel is used. For the period May 1 through September 15, the maximum vapor pressure limits issued by the US EPA are specified for each geographical area except Alaska and Hawaii. Variation of AKI with seasonal climatic changes and altitude is discussed in Appendix X1 of D-4814. This specification neither necessarily includes all types of fuel that are satisfactory for automotive vehicles, nor necessarily excludes fuels that can perform unsatisfactorily under certain operating conditions or in certain equipment. The significance of each of the properties of this specification is shown in Appendix X1 of D-4814.

The spark-ignition engine fuels covered in this specification are gasoline and its blends with oxygenates such as alcohols and ethers. This specification does not apply to fuels that contain an oxygenate as the primary component, such as fuel methanol (M85). The concentrations and types of oxygenate are not specifically limited in this specification. However, depending on oxygenate type, as oxygenate content increases above some threshold level, the likelihood of vehicle problems also increases. The composition of both unleaded and leaded fuel is limited by economic, legal, and technical considerations, but their properties, including volatility, are defined by this specification. In addition, the composition of unleaded fuel is subject to the rules, regulations, and CAA waivers of the US EPA. With regard to fuel properties, including

volatility, this specification can be more or less restrictive than the US EPA rules, regulations, and waivers. Refer to Appendix X3 of the Standard for discussions of US EPA rules relating to fuel volatility, lead and phosphorous contents, and use of oxygenates in blends with unleaded gasoline. Contact US EPA for the latest versions of the rules and additional requirements.

D-4814 represents a description of automotive fuel as of the date of publication. The specification is under continuous review, which can result in revisions based on changes in fuel, automotive requirements, or test methods, or a combination thereof. All users of this specification, therefore, should refer to the latest edition.

7.12.2 D4815-a Determination of Methyl Tertiary Butyl Ether, Ethyl Tertiary Butyl Ether, Tertiary Amyl Methyl Ether, Diisopropyl Ether, Tertiary Amyl Alcohol and C_1 to C_5 Alcohols in Gasoline by Gas Chromatography

This test method is designed for the determination of ethers and alcohols in gasolines by GC. Specific compounds determined are: MTBE, ETBE, TAME, DIPE, methanol, ethanol, isopropanol, *n*-propanol, isobutanol, *tert*-butanol, *sec*-butanol, *n*-butanol, and *tert*-pentanol (*tert*-amylalcohol).

Individual ethers are determined from 0.1 to 20.0 mass%. Individual alcohols are determined from 0.1 to 12.0 mass%. Equations used to convert to mass percent oxygen and to volume percent of individual compounds are provided. Alcohol-based fuels such as M-85 and E85, MTBE product, ethanol product and denatured alcohol are specifically excluded from this method. The methanol content of M-85 fuel is considered beyond the operating range of the system.

Benzene, while detected, cannot be quantified using this test method, and must be analyzed by alternate methodology (Test Method D-3606 or D-4420).

Test Method D-4815 also includes procedures for calculating mass oxygen content and oxygenate concentration in volume percent. Appendix X4 of the method provides a procedure for calculating the mass oxygen content of a fuel using measured oxygenate type, oxygenate concentration in volume percent, and measured density or relative density of the fuel.

7.12.3 D5599 Determination of Oxygenates in Gasoline by Gas Chromatography and Oxygen Selective Flame Ionization Detection

This test method covers a GC procedure for the quantitative determination of organic oxygenated compounds in gasoline which have a FBP not greater than 220 °C and oxygenates which have a bp limit of 130 °C. It is applicable when oxygenates are present in the 0.1–20% by mass range.

D-5599 is intended to determine the mass concentration of each oxygenate compound present in a gasoline. This requires knowledge of the identity of each oxygenate being determined (for calibration purposes). However, the oxygen-selective detector used in this test method exhibits a response that is proportional to the mass of oxygen. It is, therefore, possible to determine the mass concentration of oxygen contributed by any oxygenate compound in the sample, whether or not it is identified. Total oxygen content in a gasoline may be determined from the summation of the accurately determined individual oxygenated compounds. The summed area of other, uncalibrated or unknown oxygenated compounds present, may be converted to a mass concentration of oxygen and summed with the oxygen concentration of the known oxygenated compounds.

7.12.4 D5622 Determination of Total Oxygen in Gasoline and Methanol Fuels by Reductive Pyrolysis

The test methods in this standard cover the quantitative determination of total oxygen in gasoline and methanol fuels by means of reductive pyrolysis methods. Precision data are provided for 1.0–5.0 mass% oxygen in gasoline and for 40–50 mass% oxygen in methanol fuels.

Several types of instrument can be satisfactory for these test methods. Instruments can differ in the way that the oxygen-containing species is detected and quantified. However, these test methods are similar in that the fuel is pyrolyzed in a carbon-rich environment.

7.13 Detection and Measurement of Nitrogen in Fuels

7.13.1 D5291 Instrumental Determination of Carbon, Hydrogen, and Nitrogen in Petroleum Products and Lubricants

D-5291 is a catch-all standard to cover the instrumental determination of carbon, hydrogen, and nitrogen in laboratory samples of petroleum products and lubricants. Values obtained represent the total carbon, the total hydrogen, and the total nitrogen.

These test methods are applicable to samples such as crude oils, fuel oils, additives, and residues for carbon, hydrogen and nitrogen analysis. These test methods were tested in the concentration range of at least 75–87 mass% for carbon, at least 9–16 mass% for hydrogen, and 0.1–2.0 mass% for nitrogen.

The nitrogen test method is not applicable to light materials or those containing <0.75 mass% nitrogen, such as hydrotreated gasoline, jet fuel, naphtha, diesel fuel, or chemical solvents. These test methods are not recommended for the analysis of volatile materials such as gasoline, gasoline–oxygenate blends, or gasoline-type aviation turbine fuels.

The results of these tests can be expressed as mass percent carbon, hydrogen or nitrogen.

Other standards of interest for fuels nitrogen analysis are:

- ISO 13379 Petroleum Products – Determination of Alkyl Nitrate in Diesel Fuels – Spectrometric Method
- ASTM D-3228 – Determination of Nitrogen by Kjeldahl Method
- ASTM D-4629 – Determination of Trace Nitrogen by X-ray Fluorescence

7.14 Detection and Measurement of Metals in Fuels

These tests are infrequently used in an era where no-lead is the preferred environment. There are instances, where native or contaminant crude-cut metal porphyrins, for example, need to be determined (they poison conversion catalysts). Appropriate test procedures are:

- ISO 3830 Petroleum Products – Determination of Lead Content of Gasoline–Iodine Monochloride Method
- ISO 6245 Petroleum Products – Determination of Ash
- ISO/FDIS 14597 Petroleum Products – Determination of Vanadium and Nickel Content – Wavelength-dispersive X-ray Fluorescence Spectrometry
- ASTM D-3231 – Determination of Phosphorus Content in Gasolines

7.15 Measurement of Fuel Densities

Although not directly a regulated quantity, the density of a petroleum stock is so important to the proper characterization of the stream that it at least needs to be mentioned. Units reported are degrees API or specific gravity. A relatively simple inspection property is given in:

- ASTM D-287 and D-1298 – Measure Density, Relative Density, or API Gravity of Crude Petroleum and Liquid Hydrocarbon Products

Output signals from certain coriolis-method flowmeters have a direct relationship between signal frequency and liquid density, but these methods are yet to be accepted as standards.

8 ON-LINE ANALYSES FOR REGULATORY CONTROL[63,67,68]

8.1 General

Some of the techniques and standards mentioned in sections 6 and 7 are strictly for laboratory-based analyses only. The techniques are either complicated, potentially hazardous, or the machinery needed to perform the analysis is large and clumsy, not at all adaptable to on-line packaging and monitoring in a modern refinery. Two techniques, however, have shown themselves to be readily adaptable to such installations. These are the spectrophotometric analysis of fuel streams by multiple IR absorption with chemometric analytical techniques and the use of fast sample systems in conjunction with GC.

Other methods besides these have been put in on-line environments, UV absorption and even LC, but these two methods hold by far the greatest interest for gasoline blenders in terms both of accuracy of method and available equipment and the wide variety of the tests they can reliably and economically perform. Therefore, the following discussion will cover these methods in detail from the standpoint of their adoption to real-time on-line monitoring.

8.2 On-line Analysis for Blender Control – Chemometric Methods[71]

This discussion is presented here, as it is critical to obtain accurate IR analytical results. IR is one of the most common of all on-line spectrophotometric methods, so the following is geared for use with on-line varieties of IR analysis, most particularly NIR methods. Other techniques for several different spectrophotometric analysis procedures beyond NIR are described previously in this work. The comments presented below are generally applicable to sample preparation and techniques for other spectrophotometric methods in general.

8.2.1 Near-infrared for On-line Gasoline Analysis – General

Near-infrared (NIR) analysis has a tremendous growth in usage for monitoring several process stream qualities of importance to gasoline blenders, in real-time. Although widespread use of NIR has been delayed by some technical challenges, refineries adapting this technology have had significant provable benefits from the installation. Significant savings derive from allowing optimal process configurations and conditions, using fewer instruments, and cost effectively measuring parameters specified by regulatory agencies.

NIR is a fast spectroscopic technique that can be put readily into industrial grade [i.e. able to withstand dust, splashing, vibration, noise, electromagnetic interference (EMI), temperature extremes – within reason] enclosures for on-line blending. NIR offers low cost per analysis in terms of time, equipment cost, and sample processing. With NIR, all analyses are completed in the time it takes to obtain a spectrum (about 1 min), regardless of how many properties are being analyzed. A single

NIR analyzer can replace multiple traditional analyzers, providing faster results. NIR can be used to monitor physical properties, such as gasoline octane number or diesel CN, or chemical properties such as the percentage of aromatics or saturates.

One of the main advantages of NIR analyzers is that they are compatible with conventional quartz fiber optics. With fiber optics, light can pass from the source to the fiber optic, then through the sample, before it is focused onto the detector. This separates the electronics of the analyzer from the sample, which is desirable, particularly when the sample is a combustible liquid. Despite the advantages of fiber optics, their use can cause difficulty for the analytical measurement. First, there is an economic incentive to place the fiber in the stream, blend header, or pipeline. If this can be done, the need for detailed sample conditioning is avoided and the cost of installing additional sample piping. A primary drawback to this strategy is that gasoline streams contain contaminants that may adversely affect the in-line probe.

Figure 13 shows a schematic plus open cabinet display of a Fourier transform NIR gasoline analyzer typical of those currently on the market.

8.2.2 Infrared Calibration – Model Validation[70,73]

Calibration of an NIR analyzer requires a training set of samples for which the properties of interest have been measured by conventional methods. For many applications, a new calibration must be done for each refinery and, sometimes, for each instrument.

Traditional analytical techniques usually depend on a single variable. NIR, on the other hand, is an example of a chemometric technique. In chemometric techniques, the property to be determined, RVP, as a good example, depends on many variables, often in complex, highly nonlinear relationships that may not always be well known before calibration begins.

Figure 13 Fourier transform NIR installation.

The process of NIR calibration begins with obtaining the NIR spectra of a training set of samples for which the properties of interest have been measured by traditional means. In the case of a set of gasoline samples, octane numbers would be measured by octane engines, RVP by Grabner cell analysis, and aromatics by laboratory FIA.

Models (equations) that relate the measured properties of the samples to their spectra are generated using a computer and statistical regression analysis or neural net software. These models allow prediction of the properties of unknown samples directly from their spectra. The model predictions are accurate, as long as the unknown samples are sufficiently similar to the training-set samples. Inaccurately predicted samples can be added to the training set to develop a revised model that has greater generality.

Model generality is less of a concern when predicting chemical composition than when predicting physical properties. This is because chemical composition is observed directly as peaks in a spectrum, whereas physical properties are inferred from a complicated correlation to their chemical composition. Generality is also less of a concern when modeling an individual process unit, such as a reformer, because the composition of the product does not vary as widely from day to day as do finished gasolines of several different grades.

Even when unknown samples are too different from the training set to permit accurate (true) predictions, NIR predictions can still be quite precise (repeatable). For those trying to control and optimize a process unit, the immediacy and precision of NIR predictions can be more important than their accuracy (where a bias can always be installed). This is particularly true when trying to determine the changes in process stream properties following a change in operating parameters.

8.2.3 Calibration – Temperature Effects

Temperature affects the analytical measurement because the amount of light absorbed by the sample is a function of the density of the material, and hydrocarbon densities change with temperature. Temperature can also affect the transmission characteristics of the fiber optic. One reason for this is that the fiber, like the sample, absorbs part of the light, and the magnitude of that absorption is a function of temperature. This is a major problem for in-stream placement of NIR sensors in that the temperature becomes as an uncontrolled variable introduced into the calibration model.

Ambient temperature is not an important factor in the transmission of digital signals by fiber optics. The user

should be aware, however, that NIR sources produce continuous light emissions in an analog fashion and that the magnitude of the output is important.

Partial compensation can be made for any of the temperature-induced inaccuracies, but the effects of temperature can greatly exceed the error of the analyzer. The variance of error so introduced by temperature is directly additive to the variance of the total system error. Therefore, like analyzer error, it must be controlled at least to the number of significant figures desired in the measured property.

8.2.4 Calibration – Reference Sampling

A final consideration that deserves attention is the type of reference scan made by the analyzer. An absorbance measurement involves the use of a reference sample to calculate a ratio. Systems that use a stored reference scan, or systems where the reference fiber optic does not experience the same environmental conditions as the sample fiber (length of fiber run, temperature changes, etc.) can add even more error to the absorbance measurement. Several refiners have historically used on-line NIR analysis successfully for conventional and ethanol-blended gasolines (a hot technical topic in the synfuel-oriented 1980s) in feedback closed-loop control. Most find that the use of a ''protofuel'' validation system is invaluable, especially when measuring multiple targets of gasoline blends. There are several ways to do this effectively.

For example, the system can be preset to run before, during, and near the end of the blending operation. If the calibration has changed, as indicated by the statistical analyses, a well-designed NIR system will correct the equations automatically and produce a printed report. This validates the on-line NIR analyzer according to ASTM D-3764.

Protofuels provide a high-quality assurance (QA). Under the best conditions, contaminants may deposit to some extent on the probe, the lamp sources may degrade slightly, and the instrument electronics or optical system may change over time. Validation with protofuels will alert a ''smart'' system and allow it automatically to correct if any of these factors start to have an effect.

Section 9.1 of this article covers sampling techniques from the viewpoint of the regulatory agencies.

8.2.5 Property Measurement Procedures – Sampling

The most common approach to component property measurement is to sample the component tank, measure the properties, and enter the values in a data table. This can take a day or more and occurs weekly or less in most plants. At least one refinery, however, samples and tests its component tanks daily.

A second less-common approach is to use results from the streams as they are released from the process units. These results are then averaged or filtered for use in blending. This process makes double use of unit analyzers or routine samples, but the tests frequently exclude important properties such as octane.

If done less often than daily, the tank-sampling method assumes that component properties are reasonably steady over several days. Both approaches assume tanks are well mixed. Unfortunately, these assumptions frequently are invalid. Component tanks are often active and usually stratified. An active tank is one into which current production goes at the same time as the blend component is drawn off. Tank stratification typically results from a minimal physical size of the tanks and the common practice of putting inlet and outlet nozzles near each other.

Properties of real components vary constantly. This variability comes from feed changes, unit upsets, day-to-night temperature swings affecting overhead condensers, and the thousand natural shocks to which units are subject.

The reason these assumptions are used is that realistic assumptions do not yield a useful calculation method. Most refiners, therefore, have decided that it is better to have useful numbers based on poor assumptions than no numbers.

8.2.6 Property Measurement Procedures – On-line Measurement

The on-line measurement of component properties has long been recognized as desirable, but up to the late 1980s the costs made it impractical for most refiners. The most important property traditionally was octane, the measurement of which with on-line knock engines is slow and capital- and labor-intensive. This provided the original impetus to install on-line control in order to reduce expensive ''octane giveaway''.

The other most critical economic qualities, RVP and distillation, were less expensive to measure on-line, but the payback for these was not as worthwhile either, until the advent of regulatory controls. US EPA Phase I and more certainly Phase II and CARB regulations have completely turned the economics of blending upside down. Now the primary factor is to minimize ''RVP giveaway'' and maximize the amount of heavier naphtha, while still meeting T90 specifications. An octane-barrel is no longer worth what it used to be and is now on last priority after the environmental regulations. While this is the way it should be for a serious ''smog-fighting'' environment, it is also one of the many reasons why reformulated fuels cost more than their petroleum-derived ancestors.

8.2.7 Other Potential Near-infrared Analysis Problems

NIR equations often ''split hairs'' to distinguish between similar-looking spectra. This high sensitivity to subtle differences between spectra means that NIR regression equations can also be sensitive to subtle differences in instrument response. Any instrument instabilities, such as slight drifts or jumps in an NIR instrument's response, can result in unacceptable deviations in the NIR predictions.

Similarly, if there is even a small difference in response between two instruments, the NIR equation developed on the first instrument will probably not work on the second without modification (i.e. calibration transfer), even if both instruments are the same make and model.

Some instrument vendors claim to have resolved the calibration transfer issue in their software or hardware. Others just limit their guarantees to certain systems and ranges of composition. Just as is the case with model generality, the simpler analysis applications are less affected by the issues of instrument stability and calibration transfer.

8.3 On-line Analysis for Blender Control – Gas Chromatography Methods

In order to satisfy a refinery's quality and regulatory control requirements, on-line analysis of several parameters are required. Perhaps the most versatile methodology for this is GC. Much time and effort has gone into this methodology for measurement of several parameters that it is necessary to know with regard to gasoline blends. The results generally show good correlation between the analyzers and the more traditional laboratory analysis methods mentioned previously in this article.

Trends in blending call for specialized gas chromatographs in gasoline and diesel blending for such qualities as V/L (vapor liquid ratio), correlated RVP, and simulated distillation correlation of ASTM D-2887 or D3710 to ASTM D-86. The correlation provided by the GC analyzer's manufacturer is tuned against laboratory results to provide continuous monitoring and evaluation for control and maintenance of ''on-spec'' blends. This improved control reduces component giveaway based on the analyzer's repeatability and accuracy. The readings from the such analyzers are consistently within 0.1–0.2 psi (0.7 to 1.38 kPa) for most gasoline grades, premium, midgrade, and regular unleaded gasoline.

With the new, more effective RVP analyzers in place, and with the addition of the octane engine and simulated distillation analyzers, gasoline properties, including octane measurements, RVP, distillation, and vapor-over-liquid ratio, can also be closed-loop controlled. As a result, gasoline blending now can be implemented with multivariable/optimization controls to capture additional benefits.

Other GC analyzers have been used with varying success in optimization of blend characteristics such as total aromatics, total sulfur, and oxygenates and benzenes to measure octane ratings.

8.3.1 Discrete Component Analyses

The GC/PIANO (paraffins, isoparaffins, aromatics, naphthenes, olefins) technique is the primary test method used for the determination of benzene, aromatics, and olefins contents of the blended gasolines. The method incorporates state-of-the-art, high-resolution GC.

The sample is injected into a capillary column, which is temperature-programmed, then separated into its components (possibly 400 or more compounds.)

The data-acquisition system and software integrate the area under each peak and normalize the data, after adjusting for detector response factors for each compound. Each peak is then grouped into one of the five Piano hydrocarbon types. Finally, a detailed list of the hydrocarbon groups and each component, in weight percent and volume percent, is produced.

8.3.2 Evaluating Distillation Using Gas Chromatography-simulated Distillation Methods

To meet the strict environmental and performance specifications of US EPA/CARB-type gasolines in blend operations, while maintaining or even improving profit margins, accurate determination of the distillation assay is essential. Refiners use D86 T50 and T90 values to set blend run operating parameters and check results. Although it is possible to determine D86 through physical distillation in the laboratory, these methods are time-consuming. One analysis can take from 2 to 6 h. In addition, physical distillation methods require at several milliliters of the product. Although it has been tried in various refining environments, on-line distillation analyzers are clumsy, difficult to maintain and calibrate, and often inaccurate. Simulated distillation provides accurate information on blend components and can be packaged in a manner conducive to continuous real-time analysis. Simulated distillations are GC determinations of the bp range of the components in a sample mixture. ASTM D-86 is the method to which most if not all gasoline is sold. While ASTM D-86 is not the only laboratory distillation method, it is the most common, since it is the easiest to perform.

Two ASTM methods, D-2887 and D-3710, described standardized GC to perform a simulated distillation assay. GC simulated distillation methods offer better distillation results and accurate information on the boiling range distribution. They also offer several operational advantages over physical ASTM methods for D86 and D1160 in the laboratory. Unless the analyst using laboratory-based

physical distillation methods follows the ASTM procedures rigorously and his or her equipment meets the test standards, the test results are too often inconsistent.

It is possible to compare the results of the various methods for determining distillation curves. ASTM method D-2892 obtains TBP results using a laboratory distillation unit with 15 theoretical plates. Simulated distillation results closely match the results obtained from ASTM D-2892. Simulated distillation and ASTM D-86 also give similar results for bps less than 400 °C.

8.3.3 On-line Reid Vapor Pressure Analysis

US EPA Phase I and II regulatory compliance needs, along with the addition of oxygenates and other local regulatory requirements, have redefined gasoline blending rules and left refineries vulnerable to millions of dollars in additional cost. Precise on-line analyzer measurement and closed-loop control of key gasoline specifications, such as RVP, are critical to efficient cost-effective blending under these circumstances.

Accurate and repeatable RVP measurements allow more low-value stocks (such as butane) to be used in the blending, without switching to more expensive blending components. Butanes are readily available, economical, and increase fuel vapor pressure as well as octane. Typically, every 0.1 psi closer to the targeted blend RVP value represents an annual saving of up to $400 000 based on 50 000 BBI/day blended.

Blended gasoline specifications must be measured either in the laboratory or on-line, where process analyzers play a key role. While other refinery processes can be closed-loop controlled using inferential methods, gasoline blending closed-loop control relies totally upon on-line analyzers. Therefore, both analyzer accuracy and reliability are critical in order to control RVP successfully with a closed-loop.

Historically, blenders used continuous mechanical (Hallikainen-type) RVP analyzers. These required intensive maintenance because of their moving parts and, despite modifications to operating procedures, and preventative maintenance, their accuracy and reliability of analytical service was still poor. The modifications included shutting down analyzers when not in use and allowing analyzers from each header to service the others when necessary in order to increase reliability.

There were significant differences between analyzer readings and laboratory results for the gasoline grab samples. There was a bias adjustment for each of the old analyzers, but because of the differences in readings, the technician had to change the bias constantly, making the closed-loop RVP control scheme difficult at best.

The on-line time of the mechanical RVP closed-loop controls was poor, usually below 50%. Because of the uncertainty of the on-line analyzer readings, the rate of RVP giveaway was typically and uneconomically high. Several GC-based analyzers and a few vapor pressure flow-cell analyzers went on the market with the necessary characteristics. A quality on-line RVP analyzer will have the following key qualifications:

1. Its repeatability is 0.005 psi and its reproducibility is 0.15 psi vs an accuracy of 0.3 psi for the old analyzer. Inferential predictive methods are no better than this either.
2. It stays on stream, with little or no maintenance.
3. Its cycle time is less than 20 min.
4. It does not require special calibration beyond standard GC methodology.
5. It incorporates up-to-date microprocessor-based technology.

The RVP controllers will typically take the analyzer signals and adjust butane or light straight run naphtha rates to meet RVP targets or set points. To ensure smooth continuous control, inferential dead-time compensated controllers should be used to treat the discrete RVP analyzer signal. The controllers are carefully tuned based on the analyzer cycle time, the response of the fast sample loop, and the system dynamic.

Because the cycle time of the RVP analyzer is about 8–20 min, the response of the RVP controller is adequate to handle most blending disturbances. Typically, the controller can control RVP within 0.1–0.2 psi (0.7 to 1.38 kPa) of the set point, as illustrated in the above graphs. The newer RVP analyzers also provide a safety check to detect analyzer failure. This is done by hardwiring the analyzer trouble alarm directly to the distributed control system (DCS). It replaces the jump check and the stagnant check to detect bad RVP signals.

Since these GC-based RVP analyzers have been installed in refineries, they have usually performed reliably. Typical problems include such incidences as leaking valves and fittings, loss of air supply to the analyzers, and so on. Required repairs after startup infancy troubles are minimal compared to the previous mechanical systems. Analyzer repeatability is good. In order continually to prove the accuracy of the analyzers, high-purity but readily and economically available reference components such as 2,3-dimethylbutane (RVP 7.8 psi) and 2,2-dimethylbutane (RVP 9.8 psi), and normal pentane (RVP 15.4 psi) should occasionally be used to check analyzer repeatability and reproducibility. Also a Graebner RVP analyzer is used to check against on-line RVP results. This is an important check because most regulatory agencies certify or require certification of results with Graebner-type analyzer measurements on the grab samples.

9 MAINTAINING QUALITY CONTROL OF ON-LINE ANALYSES

9.1 Blend Certification Sampling and Testing Procedures

Samples that accurately represent batch properties are necessary in order to determine if regulatory standards are being met. Several book references and standards describe how to do sampling properly so a general treatise on this topic will not be pursued here. It is useful, however, to consider how the regulatory agencies prefer to specify testing procedures.

CARB regulations state[77] that ''each refiner or importer shall determine the value of each of the [RFG] properties for each batch of RFG it produces or imports prior to the gasoline leaving the refinery or import facility, by collecting and analyzing a representative sample of gasoline taken from the batch.'' ''Batch of reformulated gasoline'' is defined at as ''a quantity of reformulated gasoline which is homogeneous with regard to those properties which are specified for reformulated gasoline certification.'' Therefore, the first concern of batch sampling is to determine whether or not the tank contents are homogeneous.

Gravity analyses of upper, middle, and lower samples are a suggested means of establishing tank homogeneity. US EPA would consider a tank to be homogeneous where the maximum difference in tested gravities between any two samples from different tank strata is no greater than 0.6 API, unless there is reason to believe the tank contents are not mixed in spite of such gravity test results. For example, if samples from a storage tank have noticeably different colors, the gasoline in the tank should not be considered homogeneous even if the samples have gravity tests that are within the 0.6 API range. If a question remains about whether the contents of a storage tank are fully mixed following gravity testing, the party could resolve the homogeneity issue by conducting tests on the upper, middle and lower tank samples for benzene and oxygen. Tank homogeneity could be established using benzene and oxygen tests on upper, middle and lower tank samples without the need for gravity testing. The US EPA would consider a tank to be homogeneous if the maximum difference in benzene tests is 0.10 vol% and the maximum difference in oxygen tests is 0.15 wt%. The benzene and oxygen testing to establish homogeneity (as opposed to certification testing) could use a nonregulatory method such as mid-IR analysis.

In cases where the tank contents are not homogeneous, further in-tank or reblend mixing should be performed before collecting a representative sample for RFG analysis. Product stratification should also be avoided downstream of refiner or importer facilities, because samples must meet the downstream ''per gallon'' standards, and stratification could result in a portion of the gasoline in a tank being out of compliance with ''per gallon'' standards.

The US EPA mandates that storage tanks should be sampled[78] using the method that will best represent the contents of the tank or batch. The refiner, importer, or independent laboratory should use its best professional judgment in determining the procedures that are necessary in order best to represent a given batch within the guidelines of its Appendix D, which contains general instructions and precautions that must be followed when choosing sampling equipment and containers, and when collecting samples.

US EPA preference for sampling storage tanks is a ''running'' or ''all-levels'' sample collected from an unconfined (no gage tube) roof port. A ''running'' or ''all levels'' sample collected from a perforated gage tube is the next best choice. In no case should a sample be collected from a solid gage tube.

US EPA prefers to collect ''running'' samples as opposed to ''all-levels'' samples for two reasons. First, assuming that both ''all-levels'' and ''running'' samples are collected with uniform lowering and retrieval rates, the ''running'' procedure achieves better representation of the tank contents than the ''all-levels'' procedure. This occurs because with the ''running'' procedure, one half of the sample is collected when lowering the apparatus, and the column sampled is undisturbed at that point. The second reason is that ''running'' samples are easier to collect than ''all-levels'' samples because the sample collector is not required to stopper the sample bottle.

If a tank cannot be bottle sampled from the top, then tap sampling is an appropriate substitute. For best representation, a single composite should be collected by proportionally filling the sample container from all available taps. If homogeneity is well documented, the entire sample may be collected from a single tap. If a refinery or importer tank has no roof sampling port or sampling taps, then a pipeline sample is the only other sampling means that is possible.

CARB inspectors obtain gasoline samples using the sampling procedure in section 2296, Motor Fuel Sampling Procedures. Generally, ''running samples'' or ''all-levels samples'' will be obtained from refinery and terminal tanks that have appropriate access from a sample hatch. ''Tap samples'' will be obtained from those tanks that do not have hatches. ''Nozzle samples'' will be obtained from service station nozzles. As to how many samples will be obtained, the CARB inspectors generally obtains two samples, one to be used for RVP analysis and the other for all the other fuel analysis.

In the case of downstream QA sampling from a storage tank which does not have a roof sampling port or taps for

sampling, a sample collected from a truck or barge that has just loaded from that tank is marginally acceptable. The truck or barge should be completely empty before loading, and a ''running'' sample should be collected from the truck or barge compartment.

RVP is the most sensitive RFG property, relative to sampling, and therefore precautions to prevent loss of ''light ends'' must be followed carefully. Also, sampling containers must be clean and rinsed well with the gasoline to be sampled, so that the sample is not contaminated, for example, with trace amounts of heavy metals. When collecting tap samples, the tap and connecting piping must be completely flushed, and the sample container must be bottom-filled strictly according to the procedure outlined in Appendix D or section 2296 depending upon the collection locality. In all cases, the sampler should label the container as soon as possible and note the location of the sampling point and method of collection. This may save several headaches at a later time if there are any questions about the measurement value or methodology.

As far as generally acceptable practices for in-line or ''pipeline'' samplings go, ASTM D-4177, *Standard Practice for Automatic Sampling of Petroleum and Petroleum Products* is probably the most applicable guidance for sampling methodology. This practice covers information for the design, installation, testing, and operation of automated equipment for the extraction of representative samples of petroleum and petroleum products from a flowing stream and storing them in a sample receiver. If sampling is for the precise determination of volatility, use Practice D5842 in conjunction with this practice. For sample mixing, refer to Practice D5854. Petroleum products covered in this practice are considered to be a single phase and exhibit Newtonian characteristics at the point of sampling.

D4177 is applicable to petroleum and petroleum products with vapor pressures at sampling and storage temperatures less than or equal to 101 kPa (14.7 psi). Refer to D5842 when sampling for RVP determination. Petroleum products whose vapor pressure at sampling and sample storage condition is above 101 kPa (14.7 psi), and liquefied gases [that is, liquid natural gas (LNG), liquefied petroleum gas (LPG) etc.], are not covered by this practice.

While the procedures covered by this practice will produce a representative sample of the flowing liquid into the sample receiver, specialized sample handling may be necessary to maintain sample integrity of more volatile materials at high temperatures or extended residence time in the receiver. Such handling requirements and procedures for sampling these fluids are described in Practice D1265, Test Method D1145, and Gas Processors' Association (GPA) 2166.

Annex A2 of 4177 contains theoretical calculations for selecting the sampler location. Annex A3 lists acceptance methodologies for sampling systems and components. Annex A4 gives performance criteria for permanent installations, while Annex A5 has the criteria for portable sampling units. Appendix X1 is a design data sheet for automatic sampling systems; Appendix X2 compares the percent sediment and water to unloading time period.

9.2 Infrared Analysis Preparation[73,79]

9.2.1 Chemometric Calibrations

Chemometric calibration techniques require substantial amounts of data for many calibrations. If this calibration data contains unknown or uncontrolled sample and spectrometer variations, the calibration requires more data with all of these variations included. Such a result may not be robust since it becomes specific, not only to the stream being measured, but also to the specific spectrometer and to the other uncontrolled variations in the system. A better calibration method is to reduce or eliminate as many sources of noise as possible. Reducing sources of variation makes the calibration simpler and more robust. The calibration models can benefit from good sample conditioning and the use of stable, properly functioning spectroscopic hardware. This fact is often overlooked at the chemometric calibration stage because techniques such as partial least squares regression (PLS) can ''fit'' noise. This does not mean, however, that the calibration models can predict noise, or deal with ''new'' noise.[50]

Systematic noise such as temperature variation or spectrometer wavelength drift can be partially modeled away by including the temperature variation or wavelength shifting in the calibration set. However, this greatly increases the size and cost of the calibration dataset.

Further, compensating for system noise in this way adds variation into the calibration dataset unrelated to the analyte. This noise in the data can mask and degrade the information of interest in spectrum, and ultimately make the analysis impossible. These issues will be discussed in detail below.

The preferred philosophy is to control as many potential sources of sample-related variations as possible. This means controlling sample, temperature, pressure, flow, particulate, and undesired phases. The sample system is used to facilitate automated true referencing and zeroing of the spectrometer. Also required is the use of a robust and well-designed spectroscopic analyzer that minimizes errors in the data due to wavelength shifts, spectral distortions, stray light, light intensity changes, or nonlinearities.

9.2.2 Sample Filtering

Sample filtering can also be crucial to quality spectroscopy. Particulate in the sample will cause scattering in the spectrum that may lead to curved, nonreproducible spectral backgrounds. A typical means of removing particulates is via centrifugal type filters with a 5–10 μm filter element. An emulsion such as water in a hydrocarbon can cause spectral scattering. This water scattering is particularly prevalent in hydrocarbons in the second and third NIR overtone regions (800–2000 nm). Water can be removed with a centrifugal-type filter. Because water is so insoluble in hydrocarbons, even a few hundred parts per million can cause scattering.

Another use for a sample system is to remove bubbles in the sample. As long as bubbles separate easily from the sample, they can be removed simply by stopping sample flow in the sample cell and allowing the bubbles to float to the top of the cell. Stop flow can also be used to eliminate the possibility of turbulent flow in the sample cell that can cause scattering due to density gradients. Turbulent flow is particularly likely in cells or probes with a path length greater than 1 mm.

It is important in sample system design that the system itself does not create bubbles. In a high volatility sample like gasoline, bubbles can be formed by a pressure drop in the system itself. Therefore flow and low-pressure control valves should be located after the sample cell. Bubbles can also be eliminated by assuring that liquid sample flow is up into the cell. This takes advantage of gravity, so that if a bubble is formed it will flow harmlessly up and out of the cell.

9.2.3 Spectrometer Maintenance

A well-designed fluid switching system can be advantageously used to maintain and monitor optical system and spectrometer performance. This allows reference fluids, protofuels, and wash solvents, as well as dry air or nitrogen to be switched into the sample cell. These functions will be required in a pending ASTM method for validation of NIR spectroscopic analyzers using chemometric-based calibrations.

Most process spectrometers designed for monitoring liquids and gases are ''single beam'' instruments. If a second reference path exists, the reference path is seldom the same as the sample path. The raw single beam spectrum obtained contains information about the sample in the sample cell and the wavelength-dependent response of the spectrometer and sample cell. To remove the effect of the spectrometer response, a spectrometer reference spectrum is required. The spectrum is ratioed against the single beam spectrum to give a spectrometer-independent spectrum. This reference spectrum is ideally a spectrum taken through the empty sample cell. It can be expected that this reference spectrum will change with time. Some changes that can affect the reference include contamination of the sample cell or ageing of the spectrometer light source. On a typical, well-stabilized spectrometer a new reference spectrum is generally recommended once every 8–24 h. This time may vary depending on the sample and the sensitivity of the calibration equations to cell contamination. Obtaining such a new reference is straightforward with a fluid switching system in place and can be an automated scheduled event that requires no manual intervention.

Obtaining a reference spectrum is accompanied by a cell wash cycle to remove sample buildup on the sample cell windows.

A typical wash and reference sequence for an on-line gasoline spectrometer follows:

1. Flush cell with toluene wash solvent – sending the toluene to the process, a flare line, or hydrocarbon waste sewer
2. Flush with pentane – other solvents may be used as long as they are volatile
3. Reverse flow through cell to top-to-bottom
4. Flush with dry nitrogen or air
5. Take the reference spectrum
6. Run diagnostics on the spectrum – if they pass, use the spectrum as the new reference, if not, alarm and keep old reference
7. Return to analysis mode.

If the spectroscopic analyzer does not have a sample system, then the sample cell or probe must be removed to be cleaned or for a reference spectrum to be obtained. Other approaches using a second optical path, such as a short-fiber loop or a dual optical path probe, exist for obtaining a reference spectrum. These approaches are all limited in that they do not take into account all the changes in the system. In particular they miss possible contamination of the sample cell or cell windows.

Depending on the configuration there are usually other assumptions as well, such as assuming that two optically different optical paths have the identical effect on the spectrum.

9.2.4 Spectrometer and Property Calibration Diagnostics

A sample system allows diagnostics of the spectrometer system itself and the property calibration equations. Such diagnostics as cell cleanliness, detector linearity, light source intensity, optical alignment, signal-to-noise, stability, and optical purge quality can all be determined automatically when a reference is taken. These tests assure that the results will be of high quality.

A sample system also allows introduction of a calibration material into the sample cell. A pure compound can be used for wavelength and cell path length checks. A measure of the overall system performance can be obtained by introducing a known sample such as a protofuel and checking the PLS prediction results.

A typical calibration cycle would be as follows:

1. execute reference cycle
2. introduce calibration fluid
3. acquire spectrum
4. run diagnostics, archive results, alarm if indicated
5. return to analysis.

9.2.5 Extractive Sampling

For gases and low-viscosity liquids, an extractive sample system provides a better quality process spectroscopic analysis. An extractive system assures spectral quality and reproducibility and a clean thermostatted sample. An extractive system allows for cost-effective sample multiplexing and automated system diagnostics. Perhaps the feature that is most important to the analysis is that such a system requires minimal manual maintenance.

Extractive sampling allows the use of an optically simple transmission cell. Pure transmission sampling is the preferred method for calibrations because of its high degree of reproducibility from cell to cell. Such a cell typically has windows sufficiently large so as not to shade off the beam. Any sample spectrum distortion due to the cell is minimized. This is crucial to eliminate the adjustment of the PLS calibrations if a cell is replaced or disassembled for cleaning. If transmission sampling is used it is possible for a technician to replace a cell without any adjustments or impact on the calibration.

Extractive sampling is a cost-effective means of sample multiplexing as compared with optical multiplexing. The use of optical multiplexing does not eliminate the need for sample conditioning. Instead, it requires multiple distributed sample conditioning systems. Multiplexing of 1–3 sample streams is common with extractive systems, and many more are possible.

There are cases where extractive sampling is not possible. This may be due to safety, sample viscosity, or very fast cycle time. If so, the preferred approach is a local extractive sample system with a fiber-optic flow-through cell. This will provide all of the sample control of other extractive systems. The use of fiber optics introduces new optical elements into the system. The characteristics of the fiber probe, optical multiplexer, fiber and fiber–spectrometer interface must be carefully controlled to assure spectral reproducibility.

9.3 Calibration and Acceptance Testing of Gas Chromatography/Simulated Distillation Analyzers for D86/Reid Vapor Pressure Analysis

Careful calibration of on-line analyzers is absolutely essential to the success of real-time fuels blending control. Performance of factory and in-field acceptance testing is a critical part of any such analyzer installation.

As part of in-field or factory acceptance tests (FAT) it is not unusual for GC/simulated distillation analyzers to behave inconsistently and show excessive deviation from laboratory data [as much as 100–150 °F (38–66 °C)]. Consequently, such analyzers are often shipped back to the manufacturer, corrected, and their performance verified using additional samples supplied by the refinery laboratory. These samples included all the sample types projected for analysis on these analyzers. Owing to time limitations, not all samples may be run on every analyzer but sufficient data was collected to be confident that the analyzers will be able to perform the required analyses with the expected precision.

Two common problems often arise in gasoline analyzer configuration. A presplitter or stabilizer flash cell may need to be added to each analyzer to prevent overloading the (typically FID) detector with samples containing high C_5 concentrations. Flow sensor placement may also present problems. Typically such sensors should be placed on the outlet side of the sample valve unless pressure relief line or cabinet space requirements dictate otherwise. Inlet flow detectors are often a source of cross-contamination of successive samples.

Acceptance criteria for the correlated D-86 data should be based upon the reproducibility of the D-86 method [15 °F/8.3 °C for initial boiling point (IBP), 19 °F/10.5 °C for FBP and 7–12 °F/3.9–6.7 °C for 10–90% distillation points]. Acceptance for computed RVP numbers is usually 0.2 psi.

Once the factory test has been validated to the proper standard, initial biases of the data can be established. Biases are a set of analyzer offsets that allow the correlation of the analyzer data with laboratory data at each reported distillation and RVP data point. These

are utilized in normal on-line analyzer operation to improve the accuracy of the analyzer data (relative to laboratory values). During normal operations, these factors should occasionally (3–6 months) be revalidated as a part of normal quality assurance (QA) standards work.

Table 14 shows an initial field acceptance test result matrix for three analyzers which failed QA standards. They were returned to the manufacturer for rework and a subsequent retest at the manufacturer's location.[80]

Tables 15 through 17 show the comparison of laboratory results with the GC analyzer distillation and RVP results for the second QA test samples. Also compiled are analyzer computed $V/L20$ data which were included in the analyzer specification as output data but were not measured by the refinery laboratory. These data, as well as the Table 14 data, are shown without any bias offsets of the data, since the statistical analysis must be done on the actual data taken by the instrument. The precision of the GC analyzer data, as measured by the SDs, is better than the precision of the laboratory data for both the distillation points and the RVP results. The pooled standard deviation for the distillation points (averaged over all equipment, samples and distillation points) was 1.1 °F/0.6 °C for the GC analyzers and 3.2 °F/1.8 °C for the laboratory distillation analyzers. For RVP, the pooled SD for the GC analyzers was 0.05 psi compared to 0.22 psi for the laboratory data. Agreement between the GC analyzer data and the laboratory distillation data was acceptable, with a few peculiar exceptions. The 10% and 20% points on the regular gasoline sample were low by 18 °F/10 °C and 13 °F/7.2 °C, respectively. In the front end of the hydrocrackate sample, the IBP was 28 °F/15.6 °C high while the 10–30% points were low. The IBP for the reformate sample was 58 °F/32.2 °C high. Of most concern was the hydrocrackate data, which showed a minimum value in the temperature vs volume% curve around 20% distilled. This appears to be due to the high C_5 content of the sample, which (according to the GC data) comprises about 40% of the sample. For RVP, agreement between the GC data and laboratory data was acceptable, with the exception of the hydrocrackate sample (probably, also due to the high C_5 content) and, marginally, the regular blend sample (0.23 psi difference probably due to the low front-end distillation points).

Fortunately, for the hydrocrackate and reformate samples (those samples with the most serious discrepancy between GC and laboratory), analytical data was

SD, standard deviation.

available for samples collected from those units over a period of time spanning about one month). This allowed a measurement of the applicability of the biases to correct the difference between the laboratory and GC data. For these samples, the bias estimations and the resulting corrected data are shown in Table 18. Here, biases are computed from the first test samples and are applied to the retest samples. These corrections produced acceptable data for all the distillation points and the RVP. It was particularly encouraging that the initial test and retest hydrocrackate samples had different bp curves and vapor pressures (indicating some change in sample composition over that period) but the bias corrections were applicable in the face of the composition change. For each sample, sets of biases will need to be determined in the field and periodically checked.

Prior data for the regular gasoline was not available to test the efficacy of the correction on that sample. However, the same deviations in distillation points and RVP were not observed in the regular initial test sample. The selection of bias corrections will represent a compromise over the range of compositions typical for a particular product or blend stock, and more data will have to be collected to determine the appropriate offsets for the regular gasoline product. Acceptable agreement could be obtained for the regular gasolines by averaging the offsets for the two regular gasolines. Nevertheless, the deviations observed in the uncorrected regular blend data could not be attributed to analyzer error.

With these results, the distillation analyzers were judged to be performing with sufficient accuracy and precision to justify acceptance of the units.

10 REFORMULATED FUELS ANALYSIS GLOSSARY

10.1 Introduction

This glossary is intended to help interested citizens understand the most commonly used air pollution terms. The glossary is divided into three sections:

1. governmental section: these terms apply to the USA unless stated otherwise
2. technical section
3. standards and associations.

10.1.1 Governmental Section

APCD (Air Pollution Control District): a county agency with authority to regulate stationary, indirect, and area sources of air pollution (e.g. power plants, highway construction, and housing developments) within a given county, and governed by a district air pollution control board composed of the elected county officials (compare AQMD).

AQMD (Air Quality Management District): a group of counties or portions of counties, or an individual county specified in law with authority to regulate stationary, indirect, and area sources of air pollution within the region and governed by a regional air pollution control board comprised mostly of elected officials from within the region (compare APCD).

Attainment area: a geographic area which is in compliance with the national and/or California Ambient Air Quality Standards (see NAAQSs or CAAQSs).

BACT (Best Available Control Technology): the most up-to-date methods, systems, techniques, and production processes available to achieve the greatest feasible emission reductions for given regulated air pollutants and processes. BACT is a requirement of NSR (New Source Review) and PSD (Prevention of Significant Deterioration).

CAAQS (California Ambient Air Quality Standard): a legal limit that specifies the maximum level and time of exposure in the outside air for a given air pollutant and which is protective of human health and public welfare (Health and Safety Code 39606b). CAAQSs are recommended by the California Office of Environmental Health Hazard Assessment and adopted into regulation by the Air Resources Board. CAAQSs are the standards which must be met per the requirements of the California Clean Air Act (CCAA).

CARB (California Air Resources Board): the state's lead air quality agency consisting of a nine-member Governor-appointed board. It is responsible for attainment and maintenance of the state and federal air quality standards, and is fully responsible for motor vehicle pollution control. It oversees county and regional air pollution management programs.

CCAA (California Clean Air Act): a California law passed in 1988 which provides the basis for air quality planning and regulation independent of federal regulations. A major element of the Act is the requirement that local APCD/AQMDs in violation of the CAAQS must prepare attainment plans which identify air quality problems, causes, trends, and actions to be taken to attain and maintain California's air quality standards by the earliest practicable date.

Emission Offset (also known as an emission trade-off): a rule-making concept whereby approval of a new or modified stationary source of air pollution is conditional on the reduction of emissions from other existing stationary sources of air pollution. These reductions are required in addition to reductions required by BACT.

Emission Standard: the maximum amount of a pollutant that is allowed to be discharged from a polluting source such as an automobile or smoke stack.

FCAA (Federal Clean Air Act): a federal law passed in 1970 and amended in 1977 and 1990 which forms the basis for the national air pollution control effort. Basic elements of the act include NAAQSs for major air pollutants, air toxics standards, acid rain control measures, and enforcement provisions.

FIP (Federal Implementation Plan): in the absence of an approved State Implementation Plan (SIP), a plan prepared by the US EPA which provides measures that non-attainment areas must take to meet the requirements of the FCAA.

NAAQS (National Ambient Air Quality Standards): standards set by the federal US EPA for the maximum levels of air pollutants which can exist in the outdoor air without unacceptable effects on human health or the public welfare.

Non-attainment Area: a geographic area identified by the US EPA and/or CARB as not meeting either NAAQS or CAAQS standards for a given pollutant.

PSD (Prevention of Significant Deterioration): a program used in development of permits for new or modified industrial facilities in an area that is already in attainment. The intent is to prevent an attainment area from becoming a nonattainment area. This program, like NSR, can require BACT and, if an CAAQS is projected to be exceeded, emission offsets.

SIP (State Implementation Plan): a document prepared by each state describing existing air quality conditions and measures which will be taken to attain and maintain NAAQSs (see AQMD).

TAC (Toxic Air Contaminant): an air pollutant, identified in regulation by the CARB, which may cause or contribute to an increase in deaths or in serious illness, or which may pose a present or potential hazard to human health. TACs are considered under a different regulatory process (California Health and Safety Code section 39650 et seq.) than pollutants subject to CAAQSs. Health effects to TACs may occur at extremely low levels, and it is typically difficult to identify levels of exposure which do not produce adverse health effects.

US EPA (United States Environmental Protection Agency): the United States agency charged with setting policy and guidelines, and carrying out legal mandates for the protection of national interests in environmental resources.

10.1.2 Technical Section-I, General

AAQS (Ambient Air Quality Standards): health and welfare based standards for clean outdoor air which identify the maximum acceptable average concentrations of air pollutants during a specified period of time (see CAAQS and NAAQS in the section 10.1.1, and Criteria Air Pollutant below).

Acute Health Effect: an adverse health effect which occurs over a relatively short period of time (e.g. minutes or hours).

Aerosol: particles of solid or liquid matter that can remain suspended in air for long periods of time because of extremely small size and lightweight.

Air Pollutants: amounts of foreign and/or natural substances occurring in the atmosphere that may result in adverse effects on humans, animals, vegetation, and/or materials.

Air Quality Simulation Model: a mathematical relationship between emissions and air quality which simulates the transport, dispersion, and transformation of compounds emitted to the air.

Air Toxics: a generic term referring to a harmful chemical or group of chemicals in the air. Typically, substances that are especially harmful to health, such as those considered under US EPA's hazardous air pollutant (HAP) program or California's Assembly Bill 1807 TAC program, are considered to be air toxics. Technically, any compound

that is in the air and has the potential to produce adverse health effects is an air toxic.

Alternative Fuels: fuels such as methanol, ethanol, natural gas, and liquid propane gas that are cleaner burning and help to meet CARB's mobile and stationary emission standards.

Ambient Air: the air occurring at a particular time and place outside of structures. Often used interchangeably with outdoor air.

BACT (Best Available Control Technology): the most up-to-date methods, systems, techniques, and production processes available to achieve the greatest feasible emission reductions for given regulated air pollutants and processes. BACT is a requirement of NSR and PSD.

Chronic Health Effect: an adverse health effect which occurs over a relatively long period of time (e.g. months or years).

Criteria Air Pollutant: an air pollutant for which acceptable levels of exposure can be determined and for which an ambient air quality standard has been set. Examples include ozone, carbon monoxide, nitrogen dioxide, sulfur dioxide, and PM-10 (Particulate Matter) (see individual pollutant definitions).

Emission Inventory: an estimate of the amount of pollutants emitted from mobile and stationary sources into the atmosphere over a specific period such as a day or a year.

Hazardous Air Pollutant (HAP): an air pollutant considered by US EPA to be particularly hazardous to health. Emission sources of HAPs are identified by US EPA, and emission standards are set accordingly.

Hydrocarbon: any of a large number of compounds containing various combinations of hydrogen and carbon atoms. They may be emitted into the air as a result of fossil fuel combustion, fuel volatilization, and solvent use, and are a major contributor to smog (also see ROG (Reactive Organic Gas)).

Inversion: a layer of warm air in the atmosphere that lies over a layer of cooler air, trapping pollutants.

Mobile Sources: sources of air pollution such as automobiles, motorcycles, trucks, off-road vehicles, boats, and airplanes (contrast with stationary sources).

Nitrogen Oxides (oxides of nitrogen, NO_x): a general term pertaining to compounds of nitric oxide (NO), nitrogen dioxide (NO), and other oxides of nitrogen. Nitrogen oxides are typically created during combustion processes, and are major contributors to smog formation and acid deposition. NO_x is a criteria air pollutant, and may result in numerous adverse health effects.

Ozone: a strong smelling, pale blue, reactive toxic chemical gas consisting of three oxygen atoms. It is a product of the photochemical process involving the sun's energy. Ozone exists in the upper atmosphere ozone layer as well as at the earth's surface. Ozone at the earth's surface causes numerous adverse health effects and is a criteria air pollutant. It is a major component of smog.

Ozone Precursors: chemicals such as hydrocarbons and oxides of nitrogen, occurring either naturally or as a result of human activities, which contribute to the formation of ozone, a major component of smog.

Photochemical Reaction: a term referring to chemical reactions brought about by the light energy of the sun. The reaction of nitrogen oxides with oxygen in the presence of sunlight to form ozone is an example of a photochemical reaction.

PM-10 (Particulate Matter): a major air pollutant consisting of tiny solid or liquid particles of soot, dust, smoke, fumes, and mists. The size of the particles (10 μm or smaller, about 0.0004 inches or less) allows them to enter the air sacs deep in the lungs easily, where they may be deposited and result in adverse health effects. PM-10 also causes visibility reduction and is a criteria air pollutant.

Pollutant Standards Index (PSI): a numerical index used for reporting severity of air pollution. The higher the index, the higher the level of pollutants and the greater likelihood of health effects.

Pollution Prevention: the use of materials, processes, or practices to reduce, minimize, or eliminate the creation of pollutants or wastes. It includes practices that reduce the use of toxic or hazardous materials, energy, water, and/or other resources.

Risk Assessment: an evaluation of risk which estimates the relationship between exposure to a harmful substance and the likelihood that harm will result from that exposure. Risk assessments are generally expressed as the estimated chance per million that a person, exposed over some period of time (e.g. a 70-year lifetime) and some specified concentration of exposure, will experience a certain effect.

ROG (Reactive Organic Gas): a reactive chemical gas, composed of hydrocarbons, that may contribute to the formation of smog. Also sometimes referred to as nonmethane organic compounds (NMOCs).

Sensitive Groups: identifiable subsets of the general population that are at greater risk than the general population to the toxic effects of a specific air pollutant (e.g. infants, asthmatics, elderly).

Smog: a combination of smoke, ozone, hydrocarbons, nitrogen oxides, and other chemically reactive compounds which, under certain conditions of weather and sunlight, may result in a murky brown haze that causes adverse health effects. The primary source of smog in California is motor vehicles.

SO_2 (Sulfur Dioxide): a strong smelling, colorless gas that is formed by the combustion of fossil fuels. Power plants, which may use coal or oil high in sulfur content, can be major sources of SO_2, SO_3 and other sulfur oxides

contribute to the problem of acid deposition. SO_2 is a criteria pollutant.

Vapor Recovery Systems: mechanical systems that collect and recover chemical vapors resulting from transfer of gasoline from operations such as tank-to-truck systems at refineries, tanker-to-pipeline systems at offshore oil operations, and pump-to-vehicle systems at gasoline stations.

VOCs (Volatile Organic Compounds): hydrocarbon compounds which exist in the ambient air. VOCs contribute to the formation of smog and/or may themselves be toxic. VOCs often have an odor, and some examples include gasoline, alcohol, and the solvents used in paints.

10.1.3 Technical Section – II

Additive: any material added to a base stock to change its properties, characteristics or performance.

Aniline Point: the lowest temperature at which equal volumes of aniline and hydrocarbon fuel or lubricant base stock are completely miscible. A measure of the aromatic content of a hydrocarbon blend, used to predict the solvency of a base stock or the CN of a distillate fuel.

Antistatic Additive: an additive that increases the conductivity of a hydrocarbon fuel to hasten the dissipation of electrostatic charges during high-speed dispensing, thereby reducing the fire/explosion hazard.

Base Stock: the base blending material, usually a straight run or refined naphtha fraction, into which additives are blended to produce finished gasolines.

Carbon Residue: coked material remaining after an oil has been exposed to high temperatures under controlled conditions.

Catalytic Converter: an integral part of vehicle emission control systems since 1975. Oxidizing converters remove hydrocarbons and carbon monoxide (CO) from exhaust gases, while reducing converters control nitrogen oxide (NO_x) emissions. Both use noble metal (platinum, palladium or rhodium) catalysts that can be ''poisoned'' by lead compounds in the fuel or lubricant.

Cetane Index: a value calculated from the physical properties of a diesel fuel to predict its CN.

Cetane Number (CN): a measure of the ignition quality of a diesel fuel, as determined in a standard single cylinder test engine, which measures ignition delay compared to primary reference fuels. The higher the CN, the easier a high-speed, direct-injection engine will start, and the less white smoking and diesel knock after start-up.

Cetane Number Improver: an additive (usually an organic nitrate) that boosts the CN of a fuel.

Cloud Point: the temperature at which a cloud of wax crystals appears when a lubricant or distillate fuel is cooled under standard conditions. Indicates the tendency of the material to plug filters or small orifices under cold weather conditions.

Compression Ratio: in an IC engine, the ratio of the volume of combustion space at bottom dead center to that at top dead center.

Copper Strip Corrosion: a qualitative measure of the tendency of a petroleum product to corrode pure copper.

Density: mass per unit volume.

Detergent: a substance added to a fuel or lubricant to keep engine parts clean. In motor oil formulations, the most commonly used detergents are metallic soaps with a reserve of basicity to neutralize acids formed during combustion.

Detergent/Dispersant: an additive package that combines a detergent with a dispersant.

Detonation: uncontrolled burning of the last portion (end gas) of the air/fuel mixture in the cylinder of a spark-ignition engine. Also known as ''knock'' or ''ping''.

Distillation: the basic test used to characterize the volatility of a gasoline or distillate fuel. For gasoline testing, ASTM D-86 is the defining standard procedure for use.

Emissions (Mobile Sources): the combustion of fuel leads to the emission of exhaust gases that may be regarded as pollutants. Water and CO_2 are not included in this category, but CO, NO_x and hydrocarbons are subject to legislative control. All three are emitted by gasoline engines; diesel engines also emit particulates that are controlled.

End Point: highest vapor temperature recorded during a distillation test of a petroleum stock.

Exhaust Gas Recirculation (EGR): system to reduce automotive emission of nitrogen oxides (NO_x). It routes exhaust gases into the carburetor or intake manifold, where they dilute the air/fuel mixture and reduce peak combustion temperatures, thereby reducing the tendency for NO_x to form.

Flash Point: minimum temperature at which a fluid will support instantaneous combustion (a flash) but before it will burn continuously (fire point). Flash point is an important indicator of the fire and explosion hazards associated with a petroleum product.

Gasohol Blend: a spark-ignition automotive engine fuel containing methanol or denatured fuel ethanol in a base gasoline. It may be leaded or unleaded.

Gasoline: a volatile mixture of liquid hydrocarbons, containing small amounts of additives and suitable for use as a fuel in spark-ignition IC engines.

Gravity: in petroleum products, the mass/volume relationship expressed as Equations (6) and (7):

$$\text{specific gravity} = \frac{\text{mass/unit volume product at } 60\,^{\circ}\text{F } (15\,^{\circ}\text{C})}{\text{mass/unit volume water at } 60\,^{\circ}\text{F } (15\,^{\circ}\text{C})} \tag{6}$$

$$\text{API gravity} = \frac{141.5}{\text{sp. gravity at } 60\,^{\circ}\text{F}/60\,^{\circ}\text{F}\ (30\,^{\circ}\text{C}/30\,^{\circ}\text{F})} - 131.5 \quad (7)$$

Hydrofinishing: a process for treating raw extracted base stocks with hydrogen to saturate them for improved stability.

Induction Period: in an oxidation test, the time period during which oxidation proceeds at a constant and relatively low rate. It ends at the point where oxidation rate increases sharply.

Inhibitor: additive that improves the performance of a petroleum product by controlling undesirable chemical reactions, i.e. oxidation inhibitor, rust inhibitor, and so on.

Insolubles: contaminants found in used oils due to dust, dirt, wear particles or oxidation products. Often measured as pentane or benzene insolubles to reflect insoluble character.

Lead: commonly used name for tetraethyl or tetramethyl lead, an additive used in gasoline to improve octane ratings. Elemental lead is commonly used in sleeve bearing and bushing alloys.

Naphthenic: a type of petroleum fluid derived from naphthenic crude oil, containing a high proportion of closed-ring methylene groups.

Octane Number: a measure of a fuel's ability to prevent detonation in a spark ignition engine. Measured in a standard single-cylinder, variable-compression-ratio engine by comparison with primary reference fuels. Under mild conditions, the engine measures research octane number (RON); under severe conditions (MON). Where the law requires posting of octane numbers on dispensing pumps, the AKI is used. This is the arithmetic average of RON and MON, $(R + M)/2$. It approximates the road octane number, which is a measure of how an average car responds to the fuel.

Octane Requirement (OR): the lowest octane number reference fuel that will allow an engine to run knock-free under standard conditions of service. Octane requirement is a characteristic of each individual vehicle.

Octane Requirement Increase (ORI): as deposits accumulate in the combustion chamber, the octane requirement index of an engine increases, usually reaching an equilibrium value after 10 000–30 000 km. Octane requirement index is a measure of the increase, which may be in the range of three to ten numbers.

Oxidation: occurs when oxygen attacks petroleum fluids. The process is accelerated by heat, light, metal catalysts and the presence of water, acids, or solid contaminants. It leads to increased viscosity and deposit formation.

Oxidation Inhibitor: substance added in small quantities to a petroleum product to increase its oxidation resistance, thereby lengthening its service or storage life; also called antioxidant.

Oxidation Stability: resistance of a petroleum product to oxidation and, therefore, a measure of its potential service or storage life.

Oxygenate: an oxygen-containing ashless organic compound, such as alcohol or ether, that can be used as a fuel or fuel supplement.

Oxygenated Fuels: fuels for IC engines that contain oxygen combined in the molecule, e.g. alcohols, ethers and esters. Term also applies to blends of gasoline with oxygenates, e.g. gasohol, which contains 10% by volume anhydrous ethanol in unleaded gasoline.

Ozone and CO Nonattainment Areas: any area of the continental USA that does not meet the 1990 CAA requirements for carbon monoxide or ground-level ozone pollutants.

Paraffinic: a type of petroleum fluid derived from paraffinic crude oil and containing a high proportion of straight chain saturated hydrocarbons. Often susceptible to cold flow problems.

Positive Crankcase Ventilation (PCV): system for removing blow-by gases from the crankcase and returning them through the carburetor intake manifold to the combustion chamber where the recirculated hydrocarbons are burned. A positive crankcase valve controls the flow of gases from the crankcase to reduce hydrocarbon emissions.

Pour Point: an indicator of the ability of an oil or distillate fuel to flow at cold operating temperatures. It is the lowest temperature at which the fluid will flow when cooled under prescribed conditions.

Pour Point Depressant: additive used to lower the pour point or low-temperature fluidity of a petroleum product.

Preignition: ignition of the fuel/air mixture in a gasoline engine before the spark plug fires. Often caused by incandescent fuel or lubricant deposits in the combustion chamber, it wastes power and may damage the engine.

Refining: series of processes to convert crude oil and its fractions into finished petroleum products, including thermal cracking, catalytic cracking, polymerization, alkylation, reforming, hydrocracking, hydroforming, hydrogenation, hydrogen treating, hydrofining, solvent extraction, dewaxing, de-oiling, acid treating, clay filtration and de-asphalting.

Rerefining: a process of reclaiming used lubricant oils and restoring them to a condition similar to that of virgin stocks by filtration, clay adsorption or more elaborate methods.

Syncrude: unconventional crudes such as those derived from tar sands, oil shale and coal liquefaction.

US EPA Complex Model: implemented on January 1, 1997. The model is more restrictive than the simple model, and contains limits on RVP, oxygen, olefins, benzene,

sulfur, and T-90. In addition, it includes requirements on aromatic content and T-50 temperatures, added in 1998.

US EPA Oxygenated Gasoline: required annually from September 15 to March 15 for use in most CO nonattainment areas. Oxygenated gasoline is defined as a spark-ignition engine fuel meeting ASTM D-4814 specifications and blended to include a minimum of 2.0% mass oxygen and a maximum of 1.0% volume benzene.

US EPA Simple Model: used to define RFG. Effective January 1, 1995. The model includes RVP and oxygen content requirements to reduce volatile organic compound emissions. It caps oxygen, benzene, sulfur, olefins, and T-90 content at levels equal to or lower than a refiner's 1990 baseline.

Vapor Pressure, Reid (RVP): measure of the pressure of vapor accumulated above a sample of gasoline or other volatile fuel in a standard bomb at 100 °F (37.8 °C). Used to predict the vapor locking tendencies of the fuel in a vehicle's fuel system. Controlled by law in some areas to limit air pollution from hydrocarbon evaporation while dispensing.

10.1.4 Associations and Standards Organizations

AAMA	American Automobile Manufacturers' Association (formerly MVMA)
ACEA	Association des Constructeurs Européens de l'Automobile (Association of European Automotive Manufacturers)
ACS	American Chemical Society
AFNOR	Association Français Pétroles de Normalisation
ANFAVEA	Auto Manufacturers' Association (Brazil)
ANSI	American National Standards Institute
APE	Association of Petroleum Engineers (USA)
API	American Petroleum Institute
ASME	American Society of Mechanical Engineers
ASTM	American Society for Testing Materials
ATC	Technical Committee of Petroleum Additive Manufacturers (Europe)
BHRA	British Hydromechanics Research Association
BNP	Bureau de Normalisation des Pétroles
BSI	British Standards Institution
BTC	British Technical Council of the Motor and Petroleum Industries (member CEC)
CARB	California Air Resources Board
CEC	Conseil Européen de Coordination pour les Developments des Essais de Performance des Lubrifiants et des Combustibles pour Moteurs (Coordinating European Council)
CEC (Finland)	Finnish Petroleum Federation (member CEC)
CEC/SB	Conseil Europen de Coordination/ Societe Belge (member CEC)
CEFIC	European Chemical Industry Council
CEN	Conseil Européen de Normalisation
CIMAC	International Council on Combustion Engines
CMA	Chemical Manufacturers' Association
CONCAWE	Conservation of Clean Air and Water (Europe)
CRC	Coordinating Research Council (USA)
CUNA	Commissione Tecnica di Unificazione nel l'Autoveicolo (member CEC)
DIN	Deutsche Industrie Norm
DKA	Deutscher Koordinierungsausschuss im Coordinating European Council (member CEC)
ECE	Economic Commission for Europe
EEB	European Environmental Bureau
EFTC	Engine Fuels Technical Committee (of CEC)
EMA	Engine Manufacturers' Association
EU	European Union
GFC	Groupement Français de Coordination (member CEC)
GRPE	Groupe des Rapporteurs pour la Pollution et l'Energie
IFP	Institute Français du Pétrole
IP	Institute of Petroleum (UK)
ISO	International Organization for Standardization
JAMA	Japan Automobile Manufacturers' Association Inc.
JARI	Japan Automobile Research Institute
JASO	Japan Automobile Standards Organization
JIS	Japanese Industrial Standards
JSAE	Society of Automotive Engineers (Japan)
NCM	National Comite Motorproeven (Netherlands) (member CEC)
NPRA	National Petroleum Refiners' Association
PAJ	Petroleum Association of Japan
SAE	Society of Automotive Engineers

SMR	Svenska Mekanisters Riksforenig (member CEC)
SNV	Schweizerische Normenvereinung (member CEC)
US EPA	Environmental Protection Agency

ABBREVIATIONS AND ACRONYMS

ACEA	Association des Constructeurs Européens de l'Automobile
AE	Atomic Emission
AET	Atmospheric Equivalent Temperature
AKI	Antiknock Index
AN	Aviation Number
ANSI	American National Standards Institute
APCD	Air Pollution Control District
API	American Petroleum Institute
AQMD	Air Quality Management District
ASTM	American Society for Testing and Materials
BACT	Best Available Control Technology
bp	Boiling Point
BPD	Barrels Per Day
Btu	British Thermal Unit
CAA	Clean Air Act
CAAQS	California Ambient Air Quality Standard
CARB	California Air Resources Board
CCAA	California Clean Air Act
CFPP	Cold Filter Plugging Point
CFR	Constant Fuel Ratio
CI	Compression–Ignition
CN	Cetane Number
CP	Paraffin Chains
CRC	Coordinating Research Council (USA)
CST	Centistokes
CW	Continuous Wave
DCS	Distributed Control System
DIPE	Diisopropyl Ether
DVPE	Dry Vapor Pressure Equivalent
EGR	Exhaust Gas Recirculation
EMF	Electromagnetic Field
EMI	Electromagnetic Interference
EP	End Point
ETBE	Ethyl Tertiary Butyl Ether
EU	European Union
FAT	Factory Acceptance Tests
FBP	Final Boiling Point
FCAA	Federal Clean Air Act
FCC	Fluid Catalytic Cracker
FFT	Fast Fourier Transform
FIA	Fluorescent Indicator Absorption
FID	Flame Ionization Detection
FIP	Federal Implementation Plan
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
GC/MS	Gas Chromatograph/Mass Spectroscopy
GPA	Gas Processors' Association
GPC	Gel Permeation Chromatography
HAP	Hazardous Air Pollutant
HPLC	High-performance Liquid Chromatography
HTSD	High-temperature Simulated Distillation
IBP	Initial Boiling Point
IC	Internal Combustion
IR	Infrared
IRVs	Ideal Resting Values
ISO	International Standards Organization
IVD	Intake Valve Deposit
LC	Liquid Chromatography
LL	Low Lead
LNG	Liquid Natural Gas
LP	Linear Program
LPG	Liquefied Petroleum Gas
MMT	Methylcyclopentadienyl Manganese Tricarbonyl
MON	Motor Octane Number
MTBE	Methyl Tertiary Butyl Ether
MVC	Multivariable Controller
NAAQS	National Ambient Air Quality Standard
NIR	Near-infrared
NMOCs	Nonmethane Organic Compounds
NMR	Nuclear Magnetic Resonance
NOISE	Nitric Oxide Ionization Spectrometry Evaluation
NSR	New Source Review
ONR	Octane Number Response
PIANO	Paraffin, Isoparaffin, Aromatic, Naphthene, Olefin (content)
PLS	Partial Least Squares Regression
PM	Particulate Matter
PN	Performance Number
PNA	Polynuclear Aromatic
PSD	Prevention of Significant Deterioration
PSI	Pollutant Standards Index
PTV	Programmed Temperature Vaporization
PVC	Polyvinyl Chloride
QA	Quality Assurance
QP	Quadratic Programming
RA	Aromatic Ring
RFG	Reformulated Gasoline
RN	Naphthene Rings
ROG	Reactive Organic Gas
RON	Research Octane Number
RVP	Reid Vapor Pressure
SAE	Society of Automotive Engineers
SD	Standard Deviation
SI	Système International d'Unitès

SIP	State Implementation Plan
SLP	Successive Linear Program
TAC	Toxic Air Contaminant
TAME	Tertiary Amyl Methyl Ether
TBP	True Boiling Point
US EPA	United States Environmental Protection Agency
UV	Ultraviolet
VOC	Volatile Organic Carbon

Crude oil at the wellhead is a hot, high pressure fluid that contains gases, oil, water vapor and solid impurities. This mixture is processed in a gas oil separator where it is brought to atmospheric pressure and separated into gases, water, solid and stabilized oil. Characterization of a stabilized crude oil is carried out using a number of analytical methods for both its physical and chemical properties. These methods include use of a densitometer for density measurement and a hydrometer for specific gravity and American Petroleum Institute (API) gravity. The densitometer provides more precise and reproducible measurement of density as well as better control of the temperature of the sample. Pour point is determined using a cooling and pouring method, water content determination by distillation, ash content by a high temperature burning method, while salt content of a crude is determined by an electrometric method. The metal contents are determined using inductively coupled plasma atomic emission spectrometry (ICPAES) and atomic absorption spectrometry (AAS). The ICPAES is faster as compared to AAS and provides simultaneous determination of a wide range of metals. The elemental analysis is carried out by oxidative combustion of the sample in which carbon, hydrogen and sulfur are measured in oxide form, while nitrogen is measured in the form of molecular nitrogen. Sulfur is also determined using atomic emission spectrometry (AES) and chemiluminescent detectors which are very sensitive as compared to the oxidative combustion method. In addition, chemiluminescent detectors also provide nitrogen determination. Molecular weight is determined using thermoelectric measurement of vapor pressure; however the values obtained are influenced by the temperature of the measurement and the type of solvent used for dissolving the sample. Gel permeation chromatography (GPC) is used for average molecular weight determination of crude oil. Physical distillation is used for producing light and middle distillates and residue fractions based on the desired boiling range or volume percent range of a crude oil as well as determination of the boiling range distribution. Gas chromatography (GC) is utilized for determination of boiling range distribution by simulated distillation, volatile compound determination and identification of crude oil spill. The faster analysis time, better reproducibility and equivalent results are some of the advantages of simulated distillation over physical distillation in the determination of the boiling range distribution of a crude oil. Gas chromatography/mass spectrometry (GC/MS) separates and identifies volatiles and low boiling components of a crude oil while mass spectrometry (MS) is utilized for assessing the molecular weights of the compounds. High-performance liquid chromatography (HPLC) is used for separation and quantification of hydrocarbon group types such as saturates, aromatics and polars. Aromatics are further separated into monoaromatics, diaromatics, triaromatics and polyaromatics. Liquid chromatography (LC) is used to fractionate the whole crude oil into desired fractions such as acids, bases and neutral nitrogen compounds. Petroleum resins are separated from whole crude oil by a liquid chromatographic method using ion-exchange resins. Liquid chromatography/mass spectrometry (LC/MS) provides separation and

positive identification of high boiling compounds of a crude oil. Supercritical fluid chromatography (SFC) is used for separation and identification of hydrocarbon group types. Compared to HPLC, SFC provides better separation of high boiling components. Infrared (IR) spectroscopy is used for determination of type of functional group and hydrogen bonding, thermal analysis for evaluating the thermal stability of the crude oils and classification of hydrocarbons while titrimetry is used for determining acid number, base number and water content.

1 INTRODUCTION

Crude oil or full range crude is a complex mixture of hydrocarbons and heteroatomic hydrocarbons which range from the simple one-carbon atom compound, methane, to highly condensed aromatics to metallic constituents such as porphyrins and asphaltenes. Crude oil at the wellhead is characterized by a hot, high velocity mixture of oil, water, hydrocarbon and nonhydrocarbon gases along with salts and sand. This mixture is then stabilized to remove gases, solids and water from oil which is a viscous brown to black liquid. The main groups of compounds present in the stabilized crude oils are: normal or straight chain alkanes (paraffins); branched alkanes (isoparaffins); cycloalkanes (naphthenes); aromatics; sulfur, nitrogen and oxygen containing compounds; and compounds having metals such as vanadium, nickel and iron. Due to this complexity, various analytical approaches are used to characterize crude oils. The characterization of the crude oil is performed either as a whole or after separating into a number of fractions based on boiling range or compound types. Analytical methods applied to whole crude oil provide information about its physical and chemical properties as well as the presence of relative amounts of different petroleum products.

2 HISTORY

The history of analytical methods starts with the discovery of crude oil. Early characterization techniques were very crude and provide limited information about the properties and composition of crude oil. These techniques and methods were more of manual type and slow and incorporated a wide variety of human errors. These methods were capable of providing only information regarding the light ends of the crude oil. The detection limit of these methods was also quite high and could not determine the trace quantities of metals and heteroatoms such as sulfur, nitrogen and oxygen present in crude oil. With the passage of time, the analytical methods became more automated and the speed and reliability of these methods are now quite high. With the introduction of high temperature methods, it became possible to identify and characterize heavy crude and residue more efficiently. Today, the analytical methods applied to crude oils are highly automated and sophisticated and provide information regarding its physical and chemical properties in a faster and more reliable manner along with very high reproducibility and repeatability.

3 TERMINOLOGY

Alkanes, also known as paraffins, are saturated compounds of carbon and hydrogen having the general formula C_nH_{2n+2}. Alkanes can be straight chain or branched.

Alkenes, also known as olefins, are unsaturated compounds of carbon and hydrogen having the general formula C_nH_{2n}. Alkanes can be straight chain or branched.

API gravity, defined by API, deg = (141.5/specific gravity 60/60 °F) −131.5.

ASTM distillation, an American Society for Testing and Materials standard laboratory batch distillation process used for determining boiling range distribution of naphtha and middle distillate carried out at atmospheric pressure.

Atmospheric residue, residue left in the true boiling point (TBP) distillation of a crude oil carried out according to ASTM D-2892.

Bottom of the barrel, the high boiling residue obtained by distillation of a crude oil.

Carbon residue, the residue formed by evaporation and thermal degradation of a carbon containing material such as crude oil or petroleum residue.

Stabilized crude oil, also known as petroleum, whole crude oil or full range crude or stabilized crude oil, is a naturally occurring liquid hydrocarbon mixture having some gaseous components and may also contain compounds of sulfur, nitrogen, oxygen, metals as well as other elements.

Cut, also called fraction, is a portion of a crude oil having a certain boiling temperature limit.

DTA, differential thermal analysis, is a technique of measuring the amount of heat evolved or absorbed as a function of temperature at which these changes take place within the material. The temperature difference between a test sample and reference material is measured as a function of temperature, while the substance and the reference material are subjected to a controlled temperature heating.

DTG, differential thermogravimetry, is a technique of measuring the amount of material loss as a function of temperature at which these changes take place within

the material. The loss of the material between a test sample and reference material is measured as a function of temperature, while the substance and the reference material are subjected to a controlled temperature heating.

FBP, final boiling point at which 99.5% of the material is evaporated.

Gas oil, a petroleum distillate product heavier than kerosene. When produced from a TBP distillation process it is atmospheric gas oil (AGO), with an approximate boiling range 190–325 °C, and from vacuum distillation it is vacuum gas oil (VGO), with an approximate boiling range 299–500 °C.

IBP, initial boiling point at which 0.5% of the material is evaporated.

Kerosene, distillate fraction which boils in the range 150–300 °C.

Light ends, low boiling hydrocarbons present in a crude oil which are mainly methane to pentane.

MBP, the temperature at which one half of the material is evaporated.

Middle distillate, distillate fraction which boils in the range 150–370 °C.

Naphtha, the distillate which boils in the range 36–200 °C.

Naphthenes, also called cycloalkanes and cycloparaffins, are cyclic compounds of carbon and hydrogen having single C–C bonds.

Sour crude, crude oil containing sulfur greater than 0.5–1.0 wt% percent or which contains a minimum of 0.05 cu ft of hydrogen sulfide per 100 gal of crude.

Vacuum residue, material left undistilled in the vacuum distillation of an atmospheric residue carried out according to ASTM D-1160.

4 COMPOSITION

4.1 Wellhead Crude Oil

Crude oil wellhead streams are usually characterized as turbulent, high temperature, high velocity mixtures of gases, oil, water vapor and solid impurities. As these streams reach the surface, they undergo continuous reduction in temperature and pressure forming a two-phase flow: gas and liquid. These streams need to be processed to separate gas and oil as well as other solid impurities present, because they are very difficult to handle, meter, characterize or transport. These streams are fed to a gas oil separator where the pressure is successively decreased in several steps and brought to atmosphere pressure. At the gas oil separator, the streams are separated into natural gas, crude oil, water and solid. These phases are then separated and analyzed for the assessment of the wellhead stream composition. The composition of the wellhead crude oil depends upon the type of reservoir and the composition of wellhead natural gas. It contains a substantial amount of hydrocarbon gases. As the pressure is reduced, these gases are released from the oil and the crude is stabilized. A typical composition of a wellhead crude oil is given in Table 1 showing the type of components and their percentage.

Table 1 Typical composition of the wellhead crude oil

Component	Mol. %
Nitrogen	0.56
Carbon dioxide	3.55
Hydrogen sulfide	1.00
Methane	45.34
Ethane	5.48
Propane	3.70
i-Butane	0.70
n-Butane	1.65
i-Pentane	0.48
n-Pentane	0.87
C_6-C_{19} compounds	24.35
C_{20+} compounds	12.32

Natural gas at the wellhead is normally associated with the oil. It may be in the form of free gas (gas not in solution) present at the top of the reservoir or dissolved in the oil (gas in solution) and its composition depends upon the type of reservoir. It is a complex mixture of hydrocarbons, mainly methane, ethane, propane and butane gases and some heavy hydrocarbons. Among these, methane and ethane are the most abundant.

4.2 Stabilized Crude Oils

Petroleum or whole crude oil is a viscous brown to black liquid mixture. The main constituents of crude oils are hydrocarbons mixed with varying amounts of heteroatomic hydrocarbon compounds. All hydrocarbon classes except alkenes are practically present in crude oils. Alkanes, cycloalkanes, mono- and polynuclear aromatics are present in crude oils. The ratio of these classes, however, differs appreciably from one crude to another. Light hydrocarbon gases such as methane and ethane may be present in small amounts dissolved in the crude or in large amounts as in associated gas. Associated gas mainly constitutes methane, ethane and propane. This gas is a valuable raw material for many petrochemicals. In addition to the hydrocarbon mixture, crude oils contain variable amounts of heteroatomic hydrocarbon compounds such as sulfur, nitrogen and oxygen compounds. These compounds, sometimes referred to as impurities, affect the ways of processing the crude as well as its market value. A refiner would prefer

Table 2 Average elemental composition (weight percent range) of stabilized crude oils

Element	Amount
Carbon	83.0–87.0
Hydrogen	11.0–14.0
Sulfur	0.05–2.50
Nitrogen	0.01–2.00
Oxygen	0.00–2.00

Table 3 Compounds present in crude oils

Compounds	Representative compounds
Hydrocarbons	
Alkanes (paraffins)	Undecane, dodecane, tricontane, tetratetracontane
Cycloalkanes (naphthenes)	Cyclohexanes, pentacyclics, hexacyclics
Aromatic/polyaromatic compounds	Pyrenes, anthracenes, phenanthrenes
Heteroatomic hydrocarbons	
Sulfur compounds	Mercaptans, thiophenes, benzothiophenes, sulfides
Nitrogen compounds	Pyrroles, pyridines, carbazoles, acridines, indoles
Oxygen compounds	Phenols, carboxylic acids, amides
Metallic compounds	
Vanadium compounds	Vanadium porphyrins
Nickel compounds	Nickel porphyrins

to process a low-sulfur crude since this will reduce the cost of hydrogen required for hydrotreatment of the products. Crude oils also contain trace amounts of heavy metals in the form of organometallic compounds and some inorganic salts, mainly sodium chloride. Some of these heavy metals, such as vanadium and nickel, are poisonous to processing catalysts. Crude oils having a high salt content are desalted before refining to reduce corrosion problems. The averaged elemental composition of stabilized crude oils is shown in Table 2. The compounds found in crude oils are given in Table 3 and generally belong to the following broad classes.

4.2.1 Hydrocarbons

The major constituents of most crude oils are hydrocarbon compounds besides minor concentrations of heteroatomic hydrocarbons. These hydrocarbon compounds are made up of hydrogen and carbon and belong to alkanes, cycloalkanes and aromatics. Alkanes, also known as paraffins, are saturated compounds having the general formula C_nH_{2n+2}. The simplest hydrocarbon compound, methane, may be present in small amounts dissolved in the crude oil. Alkanes are both straight chain as well as branched types. Branched hydrocarbons in the naphtha range are more valuable as gasoline constituents compared to the straight chain isomers since they have higher octane number. Branched hydrocarbons have lower boiling points as compared to the straight chain isomers. Cycloalkanes, also called cycloparaffins or naphthenes, are normally present in crude oils in variable proportions. Cyclohexane, substituted cyclohexanes and substituted cyclopentanes are found in the naphtha fractions. Cycloalkanes are relatively more stable than alkanes Aromatic compounds are normally present in all crude oils regardless of their type. However, C_6-C_8 mononuclear aromatics which are present in naphtha have commercial importance. These include benzene, toluene, xylenes and ethylbenzenes. The simplest aromatic compound, benzene (C_6H_6), is one of the basic raw materials for petrochemical production. Aromatics in this range are not only important petrochemical feedstocks but are also valuable motor fuels. Polynuclear aromatic compounds are present in heavier petroleum fractions and residues. Asphaltenes that are concentrated in heavy fuel oils and asphalt are polynuclear aromatics of a complex structure. It is known that condensed-ring aromatic hydrocarbons and heterocyclic compounds are the major constituents of asphaltenes.

4.2.2 Heteroatomic Hydrocarbons

Many types of heteroatomic hydrocarbon compounds occur in crude oils. The most important are sulfur, nitrogen and oxygen compounds. Metals are also present in trace amounts, mainly in the form of organometallic compounds such as vanadium and nickel porphyrins. Sulfur present in crude oils is mainly in the form of nonacidic organosulfur compounds. Sulfur compounds present in crude oil include mercaptans, sulfides, disulfides, thiophenes, benzothiophenes and dibenzothiophenes. Sour crudes contain a high percentage of hydrogen sulfide which is acidic in nature. However, many of the organosulfur compounds are not thermally stable and hydrogen sulfide is produced during crude processing. High-sulfur crudes are less valuable since they require an additional cost for the removal of sulfur compounds. During hydroprocessing of petroleum products, hydrodesulfurization (HDS) takes place and the sulfur present in the heteroatomic compounds is converted into hydrogen sulfide. Naphtha fed to catalytic reformers is hydrotreated to reduce sulfur compounds to ppm levels to ensure a long life-cycle for the expensive reforming catalysts. Nitrogen compounds present in crude oils are usually low in

concentration and range from simple compounds such as pyridine and pyrrole to more complex structures such as porphyrins. The complex structures of porphyrins are usually found in heavy fuel oils and residues. Nitrogen compounds are basic, neutral and acidic types. These compounds are thermally more stable than the sulfur compounds. During hydroprocessing of petroleum products, hydrodenitrogenation (HDN) takes place and the nitrogen present in the heteroatomic compounds is converted into ammonia. Oxygen compounds in crude oils are more complex than sulfur compounds. Most oxygen compounds are weakly acidic, such as phenol, cresylic acid and naphthenic acids. The total oxygen content of many crudes is very low. Nonacidic compounds such as esters, ketones and amides are less abundant than acidic compounds. Many of these oxygen compounds, however, are concentrated in the heavier portion of the crude. Many metals are found in crude oils; some of the more abundant are sodium, calcium, magnesium, aluminum, iron, vanadium and nickel. These normally occur in the form of inorganic salts such as sodium chloride, or in the form of organometallic compounds such as vanadium and nickel porphyrins, or in the form of salts of carboxylic acids, as in the case of calcium and magnesium. The organometallic compounds are usually concentrated in the heavier fractions and in crude oil residues.

5 CHARACTERIZATION METHODS

The whole crude or full range crude can be analyzed by a number of analytical methods. These analytical methods have been standardized by a number of societies and organizations such as ASTM, Institute of Petroleum (IP) and API. Among them, the ASTM provides a more comprehensive coverage of the analytical methods used for physical and chemical analysis of crude oils. Table 4 shows a summarized list of standard analytical methods used for the characterization of a crude oil. Figure 1 illustrates the variety of analytical techniques which are applied to characterize crude oils. Table 5 shows some of the properties of Arab Heavy and Alamein crude oils.

Table 4 A summary of standard analytical methods applied to crude oils and the type of information obtained

Test	ASTM method	Information obtained
Densitometer method	ASTM D-5002	Density
Hydrometer method	ASTM D-287	Specific gravity and API gravity
Hydrometer method	ASTM D-1298	Density, specific gravity and API gravity
Pour point	ASTM D-97	Determination of low temperature flow property
Electrometric method	ASTM D-3230	Salt content as sodium chloride
Ash content by combustion	ASTM D-482	Metal salts present
Ramsbottom carbon residue	ASTM D-524	Carbonaceous material present
Conradson carbon residue	ASTM D-189	Carbonaceous material present
Molecular weight	ASTM D-2503	Average molecular weight
TBP distillation	ASTM D-2892	Determination of boiling range distribution and collection of fractions for further characterization
Vacuum distillation	ASTM D-1160	Boiling range distribution and collection of fractions for further characterization
Physical distillation	ASTM D-95	Water content
Simulated distillation	ASTM D-5307	Boiling range distribution
Extraction	ASTM D-473	Amount of sediments
Filtration	ASTM D-4807	Amount of sediments
Asphaltene content	IP 143	*n*-Heptane insoluble present
Centrifuging method	ASTM D-96	Water and sediment content
XRF	ASTM D-4294	Sulfur content
Bomb method	ASTM D-129	Sulfur content
Atomic absorption spectroscopy	ASTM D-4628	Metal content
Atomic emission spectroscopy	ASTM D-5623	Sulfur and nitrogen content
Inductively coupled plasma atomic emission spectroscopy	ASTM D-5600	Metal and sulfur content
Potentiometric Karl Fischer titration	ASTM D-4377	Water content
Coulometric Karl Fischer titration	ASTM D-4928	Water content
Potentiometric titration	ASTM D-664	Acid number (acidity)
Potentiometric titration	ASTM D-2896	Base number (basicity)

5.1 Physical Methods

5.1.1 Density, Specific Gravity and American Petroleum Institute Gravity

The density, specific gravity and API gravity is a rough measure of the quality of a liquid product. A high value of density or specific gravity and a lower value of API gravity would normally mean a heavy crude oil containing a lower percentage of the valuable light and middle fractions and a higher percentage of residue.

The density of a crude oil is the mass to volume ratio and is usually expressed in grams per milliliter ($g\,ml^{-1}$). The density of a crude is measured by a number of methods. These include the hydrometer method[1] in which the crude oil sample is adjusted for its temperature and then poured into a cylinder.

Table 5 Properties of Arab Heavy and Alamein crude oils

Property	Arab Heavy (Saudi Arabia)	Alamein (Egypt)
API gravity at 15.5/15.5 °C (60/60 °F)	28.0	33.4
Carbon residue (wt%)	6.8	4.9
Sulfur content (wt%)	2.8	0.86
Nitrogen content (wt%)	0.15	0.12
Pour point (°C)	−23.8	1.7
Ash content (ppm)	120.0	40.0
Iron (ppm)	1.0	0.0
Nickel (ppm)	9.0	0.0
Vanadium (ppm)	30.0	15.0

The appropriate density range hydrometer is lowered into the sample and allowed to settle until temperature equilibrium is reached. Then, the hydrometer scale is read and the temperature of the sample is recorded. Temperature equilibration is achieved quickly by putting the cylinder in a constant temperature bath. Another method specifies a standard test procedure for density and relative density measurement of crude oils by digital densitometer. In this method, a crude oil sample is introduced into an oscillating sample tube and the change in oscillating frequency with respect to change in mass of the tube is measured. The density of the sample is determined by comparing the measured sample response with the calibration data produced using a standard liquid sample.[2] Specific gravity is measured directly using the ASTM D-1298 method utilizing the hydrometers graduated by specific gravity units. Specific gravity can also be obtained by converting the density values obtained using the above mentioned ASTM D-1298 method. The petroleum measurement tables are used for converting density into specific gravity and API gravity, and vice versa.[3] API gravity is determined using the API hydrometer as the basis of determination.[4] This method is similar to the above mentioned method[1] except that the hydrometers used are graduated by API gravity units. The API gravity is converted to specific gravity and vice versa by employing Equation (1)

$$\text{API gravity, deg} = \left(\frac{141.5}{\text{specific gravity } 60/60\,^{\circ}\text{F}}\right) - 131.5 \quad (1)$$

5.1.2 Pour Point

The pour point of a crude oil is an index of its low temperature mobility. The lowest temperature at which an oil can flow or pour when it is chilled without disturbance under controlled conditions is called the pour point. Pour point is determined by cooling the sample in a glass tube at a specified rate and then examining periodically for its flow characteristics.[5]

5.1.3 Salt Content

There is a great variation in the salt content of crude oils depending mainly on the oilfield source, and possibly on the producing wells or zones within a field. The determination of the salt content of crude oil requires careful sampling. Salt content, expressed as sodium chloride, indicates the amount of salt dissolved in water. Salt content of a crude oil is determined electrometrically and is based on the conductivity of the crude oil solution. In this method, the sample is dissolved in a mixed polar solvent and then subjected to an alternating electrical stress. The flow of current is measured and the salt content is determined by comparing with a calibration curve of current versus salt content for a number of standard mixtures.[6]

5.1.4 Ash Content

The ash content of a crude oil is an indication of metals and salts present as well as dirt and rust. The ash is usually in the form of metal oxides, stable salts and silicon oxides. The ash content is determined by burning a weighed quantity of whole crude oil sample contained in a high temperature resistant container in an atmosphere of air until the residue consisting of ash and carbon remains. The residue left is reduced by heating at 775 °C in a muffle furnace, then cooled and weighed.[7]

5.1.5 Carbon Residue

Carbon residue is a rough indication of the asphaltic compounds and the materials that do not evaporate under conditions of the test, such as metals and silicon oxides. Carbon residue is the residue left after coking and cracking reactions occur during heating of the sample. Conradson carbon residue is determined by subjecting a sample of crude oil to destructive distillation in a crucible for a specified time period under a heating program.[8] Ramsbottom carbon residue is obtained by quick heating of the crude oil sample contained in a glass bulb to 550 °C for a specified time period.[9] Both of these methods provide a variable amount of carbon residue for a given sample. A correlation has been developed by the ASTM which shows that the difference between the two results decreases with increasing the amount of carbon residue in the sample.[9]

5.1.6 Molecular Weight

Molecular weight is determined using a number of methods that include GPC, ultracentrifugation, electron microscope studies and MS. One of the most frequently used methods is the thermoelectric measurement of vapor pressure of a series of solutions of crude oil

in an appropriate solvent. This method is also known as vapor pressure osmometry (VPO). A number of solutions having different concentrations of crude oil are prepared in pure solvent to measure their response. Generally, the solvents used for dissolution should be stable at the temperature of measurement and should not react with the crude oil sample. Some of the solvents frequently used are benzene, toluene, chloroform and 1,1,1-trichloroethane. Prior to proceeding with the crude oil solutions, a calibration curve is developed using a number of standard solutions of benzil in the same solvent in which the sample is dissolved. This calibration curve is used to determine the molecular weight of the crude oil.[10] The value of the molecular weight from VPO must be weighed carefully because the measured value of molecular weight is a function of temperature and the molecular properties of the solvent. Higher dissolution of the crude oil is generally achieved in polar solvents, which leads to dissociation of the molecules and therefore results in low values of molecular weight. On the contrary, nonpolar or less polar solvents allow association of the molecules and therefore high molecular weights are obtained. Another method used for average molecular weight determination is GPC in which the whole crude oil sample is dissolved in an appropriate solvent. Some of the solvents which give best results in terms of solvency and suppression of interfering sorption effects are chloroform and benzene each containing 5% methanol. Other solvents such as trichlorobenzene, pyridine and methylnaphthalene are also used. The solution is filtered and introduced into the column where separation is achieved by the increasing size of the molecules and a plot of elution volume versus detector response is obtained. By comparing the elution volume of a standard sample with an unknown whole crude oil chromatographed under the same conditions, the average molecular weight is determined.[11]

5.1.7 Water Content

Another standard method that utilizes a physical distillation technique is the determination of water present in the crude oil.[12] In this method, a known amount of crude oil sample is mixed with a suitable water-immiscible solvent such as methanol and heated under reflux to boiling. The water is condensed in a graduated trap and measured.

5.2 Extraction, Filtration and Centrifuging Methods

5.2.1 Sediment Content

The sediment present in a crude oil is important for the refining as well as trading point of view. The amount of sediment is determined by extracting with a hot organic solvent in a refractory thimble.[13] Sediment is also determined by the membrane filtration method. In this method, the sample is dissolved in hot toluene and filtered under vacuum through a 0.45-μm porosity membrane filter. The filter with residue is washed, dried and weighed to obtained the amount of sediment present in the sample.[14]

5.2.2 Asphaltene Content

Asphaltenes present in a crude oil are also separated using an *n*-alkane precipitation/extraction method in which crude oil sample is dissolved in an *n*-alkane solvent such as *n*-hexane, and the mixture is stirred for an hour at ambient temperature for dissolution. The *n*-alkane solvent acts as a precipitating agent and the choice of the solvent ranges from *n*-pentane to *n*-decane. In this process, the asphaltenes are precipitated. The resulting mixture is centrifuged at 2000 rpm to separate *n*-alkane-insoluble materials from the soluble portion of the crude oil. Then the solvent containing the soluble portion of the crude oil is decanted. To the insoluble portion, more solvent is added, stirred and the mixture is again centrifuged. This process is repeated until all the insoluble material is separated from the soluble portion of the crude oil. The insoluble portion of the asphaltenes obtained is then soxhlet extracted with the same solvent for 24 h to purify the asphaltenes.[15]

5.2.3 Bottom Sediments and Water

Centrifuging is a process in which the sample contained in a tube is subjected to a force which allows different phases of a mixture to separate from each other. Water and sediments are determined using a method in which a known amount of crude oil is mixed with a water-saturated solvent such as toluene. The mixture is shaken well and then centrifuged in a graduate glass tube at a rate of 1500 to 2000 rpm. The water and sediments are separated from the crude oil, collected at the bottom of the tube and then measured.[16]

5.2.4 Heavy Hydrocarbon Content

Supercritical fluid extraction is a method in which a sample is subjected to extraction by a solvent under supercritical conditions. This method is operated at low temperature using low boiling point solvents such as carbon dioxide as an extracting medium. This method provides the extraction of nondistillable portions of crude oils which are then analyzed using other techniques.[17]

5.2.5 Petroleum Resin Content

Petroleum resins are separated from the whole crude oil or heavy fraction using a liquid chromatographic separation method known as SARA. The abbreviation SARA

is derived from the abbreviations of the main fractions separated from whole crude oil, namely: saturates, aromatics, resins and asphaltenes. In this method, a glass percolating column is packed dry with anionic exchange material Amberlyst 29 at the bottom, and a ferric chloride bound kaolin clay layer in the middle section. The upper part of the ferric chloride bound kaolin clay is packed with anionic exchange material Amberlyst 29 followed by cationic exchange material Amberlyst 15. The column is then purged with nitrogen gas flow followed by *n*-pentane elution and recycling to remove air bubbles and impurities of the packing materials. A weighed quantity of the sample is placed in a cellulose thimble and introduced into the top reservoir of *n*-pentane. The maltenes present in the sample are dissolved in *n*-pentane, leached out of the thimble and carried into the column while *n*-pentane-insoluble asphaltenes remain in the thimble. The resins are retained on the column while the oil remains unretained and collects in the bottom flask. Chloroform elution is then used to remove the resins from the column and then evaporated under nitrogen to recover the resins.[18]

Figure 2 Recycling liquid chromatographic column. (Reprinted from ASTM D-4928,[54] with permission of Marcel Dekker, Inc.)

5.3 Fractionation

Crude oil is a complex mixture of hydrocarbons and nonhydrocarbon-containing sulfur, nitrogen, oxygen and metals such as vanadium, nickel and iron. Crude oil is so complex that it contains basic as well as acidic compounds at the same time. The complexity of crudes increases with increasing boiling point. This is because as the carbon number of molecules increases, the number of isomers increases exponentially. The complexity is also enhanced due to the presence of heteroatomic and metallic compounds. Due to this complexity, crude oils are separated into fractions based upon the type of information required. There are several separation schemes used to produce fractions containing specific compound types. For example, the ion-exchange resins are used to separate acidic and basic compounds whereas ferric chloride–Attapulgus clay complex separates neutral nitrogen compounds.

The United States Bureau of Mines (USBM)–API method[19] provides separation of heavy distillates of a crude oil into saturates, acids, bases, neutral nitrogen compounds and monoaromatic, diaromatic and polyaromatic compounds. This method combines ion-exchange, coordination and adsorption chromatography and the recycling chromatographic column used for this method is illustrated in Figure 2. The crude oil sample is first distilled to produce the distillate which is passed through a glass column having anion resins where the acidic compounds are retained by the resin and other components are washed from the resin by the solvent. The retained acids are removed from the resins using elution with benzene, followed by methanol and finally with methanol saturated with carbon dioxide. Similarly, the acid-free sample is passed through a column of cationic resin to separate basic compounds from the sample. The retained bases are removed from the resin using elution with benzene, followed by methanol and finally with methanol mixed with isopropylamine. The neutral nitrogen compounds are separated by passing the sample through a column having ferric chloride–Attapulgus clay at the top and anion resin at the bottom. The nitrogen compounds are retained by making a complex with the ferric chloride–Attapulgus clay while the aromatics are washed. The retained nitrogen compound–ferric chloride complex is removed by dichloroethane elution and then broken down on contact with anion resin into ferric chloride and nitrogen compounds. The salt is retained by the resin while the nitrogen compounds are recovered. The sample left after acid, base and neutral nitrogen compound removal is chromatographed on a column packed with alumina gel in the bottom and silica gel at the top and eluted with nonpolar to polar solvent. Saturates are eluted using *n*-heptane elution, followed by *n*-heptane containing 5% benzene elution to remove monoaromatics. Diaromatics are separated by increasing the benzene content of the solvent to 15% and finally the polyaromatics are eluted with methanol containing 25% benzene and 25% ether.

5.4 Distillation

The distillation of a crude oil is carried out to determine the boiling range distribution of a crude oil as well as collection of fractions for further characterization using different analytical techniques. This is an important requirement in the preparation of an assay of a crude oil. This information is used to estimate the yield of refinery products and thus the economics of using a crude oil in the refinery. The distillation is carried out by a combination of TBP distillation and vacuum distillation.[20,21] This process is also called physical distillation to distinguish it from simulated distillation. During physical distillation, the crude oil is distilled into various fractions based upon the desired boiling range and it is accomplished in two steps: TBP distillation[20] and distillation under vacuum.[21] The TBP distillation of whole crude oil is achieved using an apparatus having a distillation column equivalent to 16 theoretical plates and operated at a 5 : 1 reflux ratio.[20] The distillation unit is provided with a boiler in which the crude oil is heated, a distillation column, a distilled fraction collector with receivers, a vacuum pump and a refrigeration unit. The distillation unit is equipped optionally with an electronic pressure sensor and a photoelectric level follower to measure the volume of distillate and distillation rate. As a first step, the absorbed gases and moisture present in the crude oil are removed from the sample before distillation and this process is called debutanization. The debutanization is performed under vacuum at 25 °C and the removed gases are trapped under cryogenic conditions. Following the debutanization of crude oil, the distillation is carried out under atmospheric pressure and increased temperature. The temperature of the crude oil in the boiler should not exceed 345 °C. Above this temperature, thermal cracking of the petroleum hydrocarbons is evident and therefore the distillation is carried out under reduced pressure. This is because at this temperature the energy required to distill a fraction exceeds the energy required to break C–C, C–H, C–S and C–N chemical bonds. The TBP distillation is carried out up to 400 °C atmospheric equivalent temperature (AET). The residue from the TBP distillation process is further distilled to produce high boiling distillates and residue.[21] This process, called vacuum distillation, is performed under reduced pressure using equipment consisting of a boiler, short column having a minimum pressure drop, a high vacuum system and a distillate receiver. The vacuum distillation is carried out up to 600 °C AET as a batch process. The collected fractions are measured and the distillation curve is prepared: per cent distilled crude oil as a function of temperature. Another method to carry out distillation under vacuum is called short path distillation. In this method, the preheated residue from atmospheric distillation is pumped at a defined rate onto the surface of a heated vertical cylinder in the evaporation chamber where it is spread by wipers into a thin, uniform and downward-falling film. The lower boiling components of the film are flash evaporated and collected in a condenser, while the higher boiling components move downward and are collected as the residue. As compared to vacuum distillation using a packed column, the short path distillation is carried out under higher vacuum, a continuous process, shorter residence time, and a shorter distance between heated and condensing surface. These factors allow very deep distillation of the residue without decomposition and a distillate fraction up to 700 °C AET is easily prepared.

5.5 High-performance Liquid Chromatography

HPLC of whole crude oil is performed to determine the amount of saturates (paraffins and naphthenes), aromatics and polars. The crude oil is first treated with an *n*-alkane solvent such as *n*-hexane to precipitate the asphaltenes. The resulting mixture is filtered through a 0.5-μm membrane filter to remove asphaltenes (*n*-alkane insolubles) from maltenes (*n*-hexane solubles). The maltenes are further fractionated using HPLC into saturates, aromatics and polars on an aminopropyl packed column. The saturates are eluted first followed by aromatics. When the aromatics are completely eluted the column is backflushed to elute the polar fraction from the column. A complete analytical HPLC run requires 30 min to elute saturates, aromatics and polars. HPLC is operated both in analytical and preparative modes. A typical HPLC system consists of sample injector, solvent delivery system, column, ultraviolet detector and a differential refractometer detector. The analytical HPLC method is used to obtain areas of saturates, aromatics and polars present in the sample solution. The saturates are detected by refractometer detector while the aromatics and polars are detected by ultraviolet detector.[22] In order to collect the fraction from HPLC for further characterization using other techniques, the preparative scale HPLC method is used. The preparative HPLC method employs wider bore columns in which a higher amount of sample can be injected, separated and the fractions collected. The collected fractions are purified by removing solvent under reduced pressure and then weighed. In another method, the whole crude oil is separated into six hydrocarbon types using a normal phase multidimensional HPLC method equipped with two columns and two switching valves. The detection of the fractions is achieved using two detectors: photodiode array detector (PAD) and evaporative light scattering detector (ELSD). These six hydrocarbon types are

1. saturates;
2. monoaromatics (1-ring);
3. diaromatics (2-ring);
4. triaromatics (3-ring);
5. quatroaromatics (4-ring);
6. polars which include 5+ rings and N- and O-heterocyclics.

The elution of components is carried out using a gradient elution program in which three solvents, namely *n*-hexane, dichloromethane and isopropanol, are used. Pure *n*-hexane is used to separate saturates and monoaromatics on a column packed with propylaminocyano (PAC) stationary phase. The aromatics are separated on a dinitroanilinopropyl (DNAP) packed column and the polarity of the solvent is gradually increased by increasing the concentration of dichloromethane in *n*-hexane. When all the aromatics are eluted, a mixture of dichloromethane and isopropanol is used to elute the polars from the column. Both columns are regenerated using a reverse elution program using all three solvents.[23]

5.6 Gas Chromatography

GC of a crude oil is performed to obtain different types of information which include determination of boiling range distribution using simulated distillation, individual component identification and identification of the source of a spilled crude oil using fingerprint chromatograms.

5.6.1 Determination of Boiling Range Distribution by Simulated Distillation Method

Simulated distillation[24] is a method in which the process of physical distillation is simulated using gas chromatographic separation of the components of the sample. This method determines the boiling range distribution of a moisture-free crude oil up to 538 °C and the material boiling above this temperature is termed residue. In this method, the crude sample is dissolved in carbon disulfide and injected into a gas chromatographic column which separates the hydrocarbons according to their boiling points. Both packed columns as well as capillary are used for separating the components. The column temperature is increased in a linear fashion and the area under the whole chromatogram is recorded. Prior to the sample run, a standard mixture of *n*-paraffins (*n*-C_5 to *n*-C_{40}), having a boiling range from 36 to 525 °C, is chromatographed under the same conditions to provide a correlation between the retention time and boiling point.[25] A comparison of the chromatogram of standard with the sample assigned boiling points to the time axis of the sample components. The amount of residue is estimated by making a second run of the crude oil sample having a known amount of internal standard consisting of C_{14}, C_{15}, C_{16} and C_{17} normal paraffins. Using these data, the boiling range distribution of the crude oil sample is calculated and reported as percent distilled versus temperature including IBP and FBP of the sample. IBP and FBP are the temperatures at which 0.5% and 95.5% of the material is eluted from the column, respectively. Figure 3 shows a simulated distillation chromatogram of Arab Berri crude oil. This method is developed further to increase the FBP of the method up to 750 °C and it is called a high temperature simulated distillation. With the introduction of high temperature resistance materials for column preparation, stationary phases and GC oven construction material, the simulated distillation is capable of analyzing crude oils up to C_{120}. In this method, an ultimetal capillary column having an operation temperature stability of 450 °C is used. This column is coated with linear polydimethylsiloxane as stationary phase and temperature programmed up to 450 °C; the hydrocarbons with boiling point up to 750 °C are then separated and identified.[26,27] In order to obtain the boiling range distribution of sulfur compounds in crude oils along with hydrocarbons, a post-column splitter is utilized to achieve detection simultaneously by both a sulfur chemiluminescent detector (SCD) and a flame ionization detector (FID).[28] A comparison of simulated distillation[24] with physical distillation[20,21] to determine the boiling range distribution of a crude oil shows that the simulated distillation incorporates a high level of automation and thus requires very little operator involvement. Besides, a single boiling range distribution analysis using physical distillation requires two to five

Figure 3 Simulated distillation chromatogram of Saudi Arabian Berri crude oil.

days whereas a complete simulated distillation analysis needed 30 min. The automation in simulated distillation analysis assures a reproducibility of 2–3 °C compared to 10–30 °C in the physical distillation process. The faster analysis time, better reproducibility and equivalent results are some of the advantages of simulated distillation over physical distillation.[29]

5.6.2 Volatile Compound Identification

The individual component identification of a crude oil is performed for volatiles using a backflushing valve system coupled with a GC system. The whole crude oil is introduced into a system with a backflushing valve. When the volatile elution is complete, the sample injected is backflushed to remove the heavy components from the column. Fast analysis of light hydrocarbons present in crude oils is performed using the switching valve, separation at sub-ambient conditions and fast temperature programming. Standard mixtures of hydrocarbons containing volatiles are used to determine the appropriate temperature and switching valve timing of the method. The crude oil is injected and the hydrocarbons up to nonane are eluted while the heavier components are prevented from entering the analytical column and sent to a system vent. This technique permits separation at sub-ambient temperatures in minimum time and the life of the column is extended.[30]

5.6.3 Oil Spill Identification

GC is also used to identify the source of oil spill. In this method, the whole crude oil is injected into a GC column with an FID. This technique provides a chromatogram having a pattern of peaks characteristic of that particular crude provided that the operating conditions remains same. An unknown or suspected spilled crude oil sample is identified by comparing its chromatogram with the standard chromatograms available for potential source crude oils. Using this technique, the source of oil spill is identified. Two-dimensional GC is used to provide better separation and identification of the crude oil components which provide both quantitative and qualitative comparison between the oil spill and the potential source crude.[31] The two-dimensional GC is combined with MS to identify the individual compounds present.[32]

5.6.4 Pyrolysis Gas Chromatography

PGC (pyrolysis gas chromatography) is a technique which provides a rapid assay of crude oil without initial treatment. This technique provides fingerprints of different crude oils for comparison purposes. In PGC, the crude oil sample is heated in a chamber to break the large molecules into smaller volatile molecules which are then separated in a gas chromatograph and characterized easily using an FID. Other detectors such as an NPD (nitrogen phosphorus detector) or an FPD (flame photometric detector) are also used for nitrogen and sulfur compound identification. A comparison of PGC and MS shows a similarity between the two techniques. In PGC, the large molecules are broken down into smaller molecules using thermal energy, whereas in MS this is done using electron impact or chemical ion impact. The molecular fragments are separated in PGC using GC whereas separation of ions is achieved in MS using a strong magnetic field. In PGC, the detection is achieved using an FID and appeared in the form of a chromatogram, whereas in MS the ions are collected and registered in the form of a profile of ions generated which is called a mass spectrum. PGC can be combined with MS to provide a better identification of the fragments obtained during pyrolysis of crude oil.[33]

5.7 Supercritical Fluid Chromatography

SFC is a chromatographic method in which the sample dissolved in carbon disulfide is injected onto a packed silica adsorption column and eluted using a highly pressurized mobile phase such as carbon dioxide. Different compounds of the sample are separated and detected using a suitable detector such as an FID. Compared to GC, SFC has the advantage of possessing a much higher solubilizing power than a gas which allows higher molecular weight and ionic compounds to be chromatographed at lower temperatures. In comparison to LC, the SFC mobile phase exhibits more desirable transport properties resulting in a significant reduction in the resistance to mass transfer in the mobile phase. Other mobile phases used in SFC include nitrous oxide, methanol, *n*-propane, *n*-butene, *n*-pentane, dichlorodifluoromethane and trichlorofluoromethane. SFC is used in the separation of polynuclear aromatic hydrocarbons and vacuum residue as well.[34]

5.8 Mass Spectrometry

In MS, the crude oil sample is placed in a vacuum chamber where a variety of methods are applied to convert the molecules into ions. These methods include fragmenting methods such as electron impact mass spectrometry (EIMS) as well as nonfragmenting techniques of field desorption mass spectrometry (FDMS) and field ionization mass spectrometry (FIMS). The ions are passed through a magnetic field and are separated according to their mass/charge ratios. The ions are collected and registered for the type and amount present in the stream. The pattern obtained after detection of ions, called the mass spectrum, is then compared with the known mass spectrum of pure compounds to find the type of compounds present in crude

oil. The mass spectrum of a crude oil is very complex since thousands of compounds belonging to different classes are present. In practice, mass spectra of the crude oil fractions are obtained which are quite useful and provide valuable information regarding the components present.[35] Low voltage high resolution is another MS method applied to distinguish between molecules of equal masses. Using this method, a nitrogen atom is easily distinguished from a CH_2 group.[36,37] The mass spectrometer coupled with GC as a detector is called GC/MS. In this technique, the compounds eluted from the GC column enter into the mass spectrum and are fragmented into ions. These ions are detected and produce a profile or mass spectrum of the compound which is then compared with mass spectra of known compounds to find its identity. The GC/MS of the whole crude is impractical since the heavy hydrocarbons present in the crude oils are not eluted from GC.

5.9 Nuclear Magnetic Resonance Spectroscopy

NMR spectroscopy analysis of a crude oil is performed to determine the type and amount of hydrogen and carbon present. NMR analysis can distinguish whether the hydrogen or carbon is attached to an aliphatic, naphthenic or aromatic type of hydrogen or carbon atom. This leads to the determination of percent paraffinic, naphthenic and aromatic hydrogen and carbon present in the crude oil. This information is quite helpful to differentiate paraffinic, naphthenic and asphaltic types of crude oils. NMR spectroscopy provides structural parameters of crude oils which can produce a detailed analysis when combined with other properties. NMR spectroscopy is performed by dissolving the sample in deuterated chloroform and adding trimethylsilane as a reference. The deuterated chloroform acts as a solvent as well as a locking agent. An NMR spectrum of crude oil is achieved by recording a magnetic resonance signal of a diluted sample in the presence of a very strong magnetic field. The combination of proton and carbon-13 NMR along with elemental analysis of crude oil allows the determination of a number of average structural parameters such as total aromatic and aliphatic carbon, naphthenic and paraffinic carbon, the number and length of paraffinic carbon chains, the degree of chain branching, the number of aromatic methyl substituents, the aromatic ring size and the degree of aromatic ring substitution.[38,39]

5.10 Infrared Spectroscopy

IR spectroscopy is used to characterize crude oils mostly in terms of oxygen and nitrogen containing functional groups. Using IR spectroscopy, acids and bases such as carboxylic acids, phenols, carbazoles and cyclic amides present in the petroleum mixtures are quantified. The type of solvent in which the crude oil is dissolved has a marked effect on the detection of different compounds. For example, tetrahydrofuran (THF) is used as a solvent to minimize association between carboxylic acids and amides and thus help in their detection in the IR spectrum.[40,41] The concentration of hydroxyl compounds is identified using the peak absorption in the region $3540–3600\,cm^{-1}$ of the IR spectrum. IR spectroscopy also determines the hydrogen bondings present between different functional groups such as OH and NH. This is done by recording the IR spectrum of the petroleum mixture at different concentrations in a number of solvents. At low concentration, the hydrogen bonding is less pronounced and the peaks of free OH ($3610\,cm^{-1}$) and NH ($3480\,cm^{-1}$) become visible.[42] IR spectroscopy is also utilized in finding the distribution of H atoms in the aromatic rings and that of CH_2 and CH groups in the aliphatic part of the hydrocarbons.

5.11 Thermal Analysis

Thermal analysis is used to study the characteristics of crude oils. During thermal analysis, a known quantity of crude oil is subjected to programmed heating in the presence of air or inert gas such as nitrogen. The crude oil sample loses moisture and volatile components by evaporation and the process behaves like the physical distillation during the initial heating. During the evaporation process, the heat is required by the molecules and thus endothermic peaks are observed in the thermogram. When the temperature of the crude oil exceeds 340 °C, thermal degradation of the oil is started due to thermal cracking of the hydrocarbons. This is because at higher temperatures the energy provided to the crude oil is enough to break chemical bonds such as C–H, C–C, C–N and C–S present in the petroleum molecules. During thermal analysis, a number of phenomena such as evaporation, decomposition and oxidation take place in the crude oil. Oxidative degradation is characterized by an exothermic peak with corresponding weight loss. Evaporation requires heat and therefore appears as an endothermic peak in the thermogram. Using thermal analysis, the hydrocarbons of a crude oil can be classified into four types; the volatiles and low molecular weight, medium molecular weight and high molecular weight hydrocarbons. The volatiles are characterized by heat absorption leading to evaporation of these hydrocarbons. The other three types of hydrocarbons are identified by the presence of exothermic peaks in the thermogram as a result of oxidative degradation of these hydrocarbons. The volatile contents of crude oils are found more in lighter crude compared to heavier crude.[43]

5.12 Elemental Analysis Method

The analysis of carbon, hydrogen, nitrogen and sulfur is very important in determining the complex nature and

type of the crude oils. Nitrogen and sulfur are very important from the processing and upgrading point of view and are determined to assess the performance of petroleum upgrading processes such as HDS and HDN. In a single instrumental method, carbon, hydrogen, nitrogen and sulfur are determined simultaneously. One of the standard methods[44] describes the determination of carbon, hydrogen and nitrogen in petroleum products. The latest development also provides determination of sulfur along with carbon, hydrogen and nitrogen. In this method, the crude oil sample is introduced into the system where oxidative combustion takes place in an oxygen–helium atmosphere. As a result, the elements C, H, N and S are converted into CO_2, H_2O, NO, NO_2, SO_2 and SO_3 product gases. These gases are passed over a copper reduction tube where oxides of nitrogen are reduced to molecular nitrogen and sulfur oxides are converted to SO_2. After the reduction process, the gas mixture contains CO_2, H_2O, N_2 and SO_2. These components are then separated using an adsorption process in which each component is adsorbed on a separate adsorption column and finally detected individually by a thermal conductivity detector (TCD). The quantification of the elements is achieved through an external standard method.

The total sulfur content of crude oils and heavy products is also determined by burning a sample in a stream of air. The sulfur dioxide produced is further oxidized to sulfuric acid, which is titrated with a standard alkali. Identification of individual sulfur compounds in crude oils is not needed from the refinery point of view since it is time-consuming and all sulfur compounds practically are hydrodesulfurized to hydrogen sulfide and hydrocarbons. Total sulfur in whole crude oil is determined using a variety of methods which include XRF spectroscopy[45] and the bomb method.[46] All of these methods have specific limitations as well as variable detection limits. In XRF spectroscopy, the sample is placed in an X-ray beam and the resulting excited characteristic radiation is measured. By comparing the signal from the sample with multilevel concentration calibration samples, the amount of sulfur present in the sample is determined. In the bomb method, the sample is oxidized by electrical ignition and combustion in a pressurized bomb filled with oxygen. All the sulfur present in the sample is converted to oxides of sulfur which are then converted to barium sulfate and determined gravimetrically.

5.13 Atomic Absorption Spectrometry

AAS is used to determine quantitatively the amount of metals present in crude oils. Generally, two methods are used for sample preparation. The crude oil sample is mixed with a suitable solvent such as mixed xylenes to produce a dilute solution. In the other method, the crude oil is heated to burn and the carbon is removed finally by heating at high temperature in a furnace. The residue is fused with a lithium tetraborate/lithium fluoride mixture. The fused sample is digested in hydrochloric acid solution and diluted with water. The diluted solution containing the metals is then aspirated into an atomic absorption spectrometer having a lamp for a particular metal or group of metals. The absorption intensity of the solution is measured individually for all the elements. Prior to the measurement of each metal, the spectrometer is calibrated using a standard solution containing the particular metal. By comparing absorption intensities of the elements present in the crude oil solution with absorption intensities measured with the standard calibration solutions, the concentrations of elements in the crude oil sample are calculated. Using this technique, almost all of the metals present in the crude oil are determined. These include aluminum, barium, boron, calcium, chromium, copper, vanadium, nickel, iron, magnesium, phosphorus, potassium, sodium, silicon and zinc.[47]

5.14 Inductively Coupled Plasma Atomic Emission Spectrometry

ICPAES is used to determine quantitatively the amount of metals present in crude oils. Generally, two methods are used for sample preparation. The crude oil sample is mixed with a suitable solvent such as mixed xylenes to produce a dilute solution. In another method, the crude oil is heated to burn and the carbon is removed finally by heating at high temperature in a furnace. The residue is fused with a lithium tetraborate/lithium fluoride mixture. The fused sample is digested in hydrochloric acid solution and diluted with water. The diluted solution is then aspirated into the ICPAES system and the emission intensities of all of the spectral lines are measured. Each spectral line represents an element while its intensity indicates its concentration present in the solution. By comparing emission intensities of elements present in the crude oil solution with emission intensities measured with the standard calibration solutions, the concentrations of elements in the crude oil sample are calculated. Using ICP, almost all of the metals present in the crude oil are determined. These include aluminum, barium, boron, calcium, chromium, copper, vanadium, nickel, iron, magnesium, phosphorus, potassium, silicon and zinc.[48,49] AES is also utilized alone for the detection and measurement of sulfur and nitrogen in crude oils. Contrary to FPD, the AES sulfur response is linear, equimolar and exhibits little or no quenching. These characteristics help in determining the concentration of total sulfur as well as individual sulfur compounds. The calibration of the detector is done using a single sulfur compound.[50] Using this detector, sulfur and nitrogen contents at low ppm levels are measured.[51]

5.15 Chemiluminescent Detection Method

A chemiluminescent detector offers rapid quantitation of speciated sulfur containing compounds in crude oils or the total sulfur present. The detector is set up either to quantify compounds separated from the crude oil or for total sulfur measurement. In this method, the whole crude is separated from asphaltenes and injected into the HPLC column where it is separated into different hydrocarbon types. The sulfur compounds present in these separated fractions are then detected by the chemiluminescent detector which is internally or externally calibrated. These compound types are detected for the presence of sulfur on a linear and equimolar basis.[52]

5.16 Titration Methods

A number of titration methods are used to determine different properties of a crude oil. These methods include determination of water content and acid and base compound concentration in a crude oil.

5.16.1 Water Content

The determination of water content is very important in the processing, transportation and purchase of a crude oil. Water content of a whole crude oil is determined using a number of methods depending upon the amount of water present in the sample. Trace quantities of water are determined by using a titration method in which the sample is titrated using Karl Fisher reagent to an electrometric end-point.[53] Ultratrace amounts of water are determined using the coulometric Karl Fisher titration method. In this method, a weight quantity of a properly homogenized crude oil sample is injected into the titration vessel of the Karl Fisher equipment in which iodine is generated coulometrically at the anode. When all the water is titrated, the excess iodine is detected by an electrometric end-point detector and the titration is complete. Since 1 mol of water reacts with 1 mol of iodine stoichiometrically, the quantity of water present in the sample is proportional to the total integrated current.[54]

5.16.2 Acid Number

The acid number of a crude oil is measured to determine the acidic constituents present, which include carboxylic acids and phenols. Acid number is defined as the measure of the amount of acidic substances present in the oil which can be determined by titration with bases under the given test conditions. In this method, a known amount of crude oil sample is dissolved in a mixture of toluene and isopropyl alcohol containing a small amount of water and titrated potentiometrically up to the end-point with alcoholic potassium hydroxide standard solution using a glass indicating electrode and calomel reference electrode.[55]

5.16.3 Base Number

The crude oils contain basic constituents such as amides, pyridines, carbazoles, etc. Base number is defined as the measure of the amount of basic substances present in the oil which can be determined by titration with acids under the given test conditions. In this method, a known amount of sample is dissolved in an anhydrous mixture of chlorobenzene and glacial acetic acid and titrated with a solution of perchloric acid in glacial acetic acid using a potentiometric titrator. The potential readings are measured by means of a glass indicating electrode and a calomel reference electrode and the end-point is detected.[56] The types of nitrogen compounds are determined using a scheme in which the sample is dissolved in a mixture of acetic anhydride and benzene in the ratio 2 : 1 and titrated with 0.05 M perchloric acid prepared in 1,4-dioxane using a glass indicating electrode and a calomel reference electrode system. A number of end-points are detected which indicate the types of nitrogen compounds titrated. Using this method, the nitrogen compounds are classified into strong bases, weak bases and nonbasic types.[57]

Simulated distillation (SimDist) is a gas chromatography (GC) technique which separates individual hydrocarbon components in the order of their boiling points, and is used to simulate the time-consuming laboratory-scale physical distillation procedure known as true boiling point (TBP) distillation. The separation is accomplished with a nonpolar chromatography column using a gas chromatograph equipped with an oven and injector that can be temperature programmed. A flame ionization detector (FID) is used for detection and measurement of the hydrocarbon analytes. The result of SimDist analysis provides a quantitative percent mass yield as a function of boiling point of the hydrocarbon components of the sample. The chromatographic elution times of the hydrocarbons are calibrated to the atmospheric equivalent boiling point (AEBP) of the paraffins reference material. The SimDist method ASTM (American Society for Testing and Materials) D2887 covers the boiling range 55–538°C (100–1000°F) which covers the n-*alkanes (*n-*paraffins) of chain length about* C_5–C_{44}*. The high-temperature simulated distillation (HTSD) method covers the boiling range 36–750°C (97–1382°F) which covers the* n-*alkane range of about* C_5–C_{120}*. A key difference between ASTM D2887 and HTSD is the ability of the latter technique to handle residue-containing samples (i.e. material boiling > 538°C, 1000°F). SimDist and laboratory-scale physical distillation procedures are routinely used for determining boiling ranges of petroleum crude oils and refined products, which include crude oil bottoms and residue processing characterization. The boiling point with yield profile data of these materials are used in operational decisions made by refinery engineers to improve product yields and product quality. Data from SimDists are valuable for computer modeling of refining processes for improvements in design and process optimization. Precise yield correlations between HTSD and crude assay distillation (methods ASTM D2892 and D5236) have allowed HTSD to be successfully used in place of physical distillation procedures. This has given the refiner the ability to rapidly evaluate crude oils for selection of those with economic advantages and more favorable refining margins. SimDist methods are becoming more widely used in environmental applications. HTSD is useful for characterizing hydrocarbons which can be present as soil and water contaminants; for example, to map and follow hydrocarbon removal processes.*

1 INTRODUCTION

SimDist is a GC technique which separates individual hydrocarbon components in the order of their boiling points, and is used to simulate time-consuming laboratory-scale physical distillation procedures. The separation is accomplished with a chromatography column coated with a nonpolar (hydrocarbon-like), stationary phase, and uses a gas chromatograph equipped with an oven and injector which can be temperature programmed. A FID is used for detection and measurement of the hydrocarbon analytes. The SimDist analysis result provides a quantitative percent mass yield as a function of boiling point of the hydrocarbon components of the sample being analyzed. The chromatographic elution times of the hydrocarbon components are calibrated to the AEBP of the *n*-alkane as described in a method from the ASTM[1] by using *n*-alkane (*n*-paraffin) reference material. In the SimDist method ASTM D2887,[1] the *n*-alkane calibration reference covers the boiling range 55–538 °C (100–1000 °F) which covers the *n*-alkanes with a chain length of about C_5–C_{44}. In the HTSD method, the *n*-alkane calibration reference (a hydrogenated polyolefin wax, polywax 655) covers the boiling range 36–750 °C (97–1382 °F) which covers the *n*-alkanes with a chain length of about C_5–C_{120}. A key difference between ASTM D2887 and HTSD is the ability of HTSD to handle residue-containing samples (i.e. material boiling > 538 °C or 1000 °F).

SimDist and laboratory-scale physical distillation methods are routinely used for determining boiling ranges of petroleum crude oils and refined products. The boiling point with yield profile data of these materials are used in operational decisions made by refinery enginers to improve product yields and product quality. SimDist is valuable for, and can improve results from, computer modeling of refining processes for improvements in design and process optimization. Precise yield correlations between HTSD and crude assay distillation (a procedure which uses methods ASTM D2892[2] and D5236[3]) have allowed HTSD to be successfully used in place of physical distillation procedures. This can result in economic advantages for the refiner in the selection of crude oils, with more favorable refining margins. SimDist methods are also now becoming more widely used in environmental applications; for example, in characterizing hydrocarbons which can be present as soil and water contaminants.

2 HISTORY

SimDist was reported early in the 1960s by Eggertsen et al.[4] and Green et al.[5,6] as a method of simulating the time-consuming laboratory-scale physical distillation "TBP" procedure[7] by using GC. The SimDist technique is based on the fundamental assumption that individual nonpolar hydrocarbon components of a sample elute in the order of their boiling points from a GC column coated with nonpolar (hydrocarbon-like), stationary phase. The elution, or retention, time is dependent upon vapor pressure of the component and its affinity for the stationary phase. This varies with different types of hydrocarbons. For example, aromatic hydrocarbons and cycloalkanes (naphthenes) generally elute earlier than *n*-alkanes having the same boiling points. In SimDist, conditions are selected to give limited column efficiency and resolution unlike other chromatography techniques, which generally aim for highly efficient conditions that achieve high-resolution separation of components. The lower resolution analysis conditions provide distillation data that agree with physical distillation.

SimDist became an ASTM standard method in 1973, with the designation D2887, "Boiling Range Distribution of Petroleum Fractions by GC". The current edition is designated D2887-97. This method covers the determination of the boiling range distribution of petroleum products and fractions having a final boiling point (FBP) of 538 °C (1000 °F) or lower at atmospheric pressure.

HTSD is a relatively recent method which extends ASTM D2887 determination of the boiling range distribution of hydrocarbons to a FBP of about 750 °C (1382 °F). Technological advances in capillary GC columns and stationary phases together with either programmed temperature vaporization (PTV) or on-column injection techniques, provide adequate separation from C_5 to C_{120} normal paraffins and allows the characterization of petroleum products from about 36–750 °C (97–1382 °F). Under the special conditions of HTSD, elution of materials from the GC column occurs at up to 260–316 °C (500–600 °F) below their AEBP. For instance, the elution of C_{110} (AEBP of 735 °C or 1355 °F) occurs at a column temperature of about 427 °C (800 °F). Also under these conditions, little or no evidence of cracking is normally seen in HTSD.

3 COMPARISON OF AMERICAN SOCIETY FOR TESTING AND MATERIALS DISTILLATION AND SIMULATED DISTILLATION METHODS

A summary of ASTM physical distillation and SimDist methods is presented schematically in Figure 1 and discussed in detail below.

3.1 Physical Distillation Methods

Laboratory-scale physical distillation methods are routinely used by petroleum refineries for determining

Figure 1 Summary of ASTM physical and simulated distillation.

the boiling ranges of crude oils and their products. ASTM D86[8] has been used as a quality control (QC) test since the 1920s. This method is a one-plate distillation that covers the range of materials boiling up to about 254 °C (490 °F). ASTM D1160[9] is a similar method but is conducted at reduced pressure and covers the determination of the range of boiling points for petroleum products that can be partially or completely vaporized at a maximum liquid temperature of 400 °C (752 °F). This temperature corresponds to an atmospheric equivalent (vapour) temperature of about 600 °C when run under 1 mmHg (the lowest pressure permitted). Petroleum products and fractions in this range may decompose if distilled at atmospheric pressure. ASTM D2892[2] is used for samples with a wide boiling range such as crude petroleum up to a final cut temperature of 400 °C (752 °F) atmospheric equivalent temperature (AET). The method can also be applied to any petroleum mixtures except liquified petroleum gases, very light naphthas, and fractions having initial boiling points (IBPs) above 400 °C. This test method uses a fractionating column having an efficiency of 14–18 theoretical plates operated at a reflux ratio of 5 : 1 for the production of liquefied gas, distillate fractions, and residuum. The method provides for the determination of yields of material as both mass and volume. A graph of temperature versus mass-percent distilled can be produced, and this distillation curve corresponds to a laboratory technique which is defined at 15/5 (15 theoretical plate, 5 : 1 reflux ratio) or TBP. ASTM D5236[3] is for distillation of heavy hydrocarbon mixtures such as heavy crude oils, petroleum distillates, residues, and synthetic mixtures with IBPs greater than 150 °C (300 °F). This method provides for the determination of standard distillation curves to the highest AET possible by conventional distillation. The maximum achievable temperature up to 565 °C (1050 °F) AET is dependent upon the heat tolerance of the charge.

3.2 Simulated Distillation Methods

SimDist methods which have been adopted as ASTM test methods are D2887,[1] D3710,[10] and D5307.[11] Method D2887-97 covers the determination by GC of the boiling range distribution of petroleum products and fractions having a FBP of 538 °C (1000 °F) or lower at atmospheric pressure. Method D3710-95 covers the determination by GC of the boiling range distribution of gasoline and gasoline components with a FBP 260 °C (500 °F) or lower. D5307-97 is for the determination by GC of boiling range distribution of crude petroleum through 538 °C (1000 °F), with material boiling above 538 °C being reported as residue.

HTSD by GC, which is currently under ASTM Committee D-2 proposed development status, is an extension of ASTM method D2887 for application to petroleum products and fractions, and materials containing higher boiling range materials above 538 °C (1000 °F). This method is used for determining the boiling point distribution of petroleum products and fractions in the range up to about 732 °C (1350 °F) at atmospheric pressure, and reports material boiling higher than this as material boiling >732 °C (1350 °F). The method is applicable to a wide range of fully eluting and non-completely eluting materials, which include petroleum crude oil, cat crack feed and product, hydrotreater feed and products, atmospheric residue, vacuum gas oils, deasphalted oils, and vacuum tower bottoms (pitch).

4 METHODOLOGY

By the proper choice of GC conditions and equipment in HTSD, separation in the boiling range from C_5 to C_{120} *n*-alkanes is carried out routinely. To accomplish the goal of eluting heavy materials up to the equivalent of C_{120}, a thin film of column nonpolar stationary phase is used. The film thickness varies from 0.05–0.15 m, which, with a 0.53 mm internal diameter (ID) capillary column results in a phase ratio (volume of the column vs the volume of the stationary phase) high enough to permit the elution of materials from the column at temperatures up to 260–316 °C (500–600 °F) below their AEBP.

GC instrumentation for HTSD is typically equipped with a PTV injector and FID. The analysis is carried out with a relatively short capillary column about 5 m length, 0.53 mm ID, and 0.05–0.15 μm film thickness. The temperature conditions of the column oven and injector are set initially at either near ambient or sub-ambient (−20 °C) and then programmed at a specified linear rate to a final temperature of about 430 °C. Sub-ambient initial conditions are generally required to cover a wide boiling range of samples. Helium carrier gas is used. The detector

signal is recorded as area slices (time intervals) for consecutive increasing retention times. SimDist software is used for data acquisition and results calculations.

4.1 Sample Preparation

A consequence of the conditions necessary for HTSD is a limited concentration capacity of the column due to the small amount of stationary phase. This requires appropriate dilution of the standards and samples (usually in carbon disulfide). Liquid hydrocarbon samples such as petroleum crude oils, gas oils, and solid or semi-solid residue materials, such as vacuum tower bottoms and asphaltic materials, are typically prepared at a concentration of about 2 mass percent in the solvent. Environmental samples such as oil-contaminated soils and waters are generally prepared at higher concentrations on the order of about 50 mass percent solvent to sample to improve sensitivity.

4.2 High-temperature Simulated Distillation Analysis

Because of the highly inert conditions of high-purity fused silica and special treated metal GC columns, the gentle injection techniques, and the short time at maximum temperature, little or no evidence of cracking is normally seen in HTSD. Because of the column breakdown (bleed) during the final portion of an HTSD analysis and the need to dilute the sample to approximately 1–2%, a blank GC run using only the solvent is recorded in the data system. This solvent blank is then subtracted from all subsequent GC runs in the analysis sequence of calibration, QC, and samples (Figure 2). This blank subtraction accomplishes

Figure 2 Analysis of carbon disulfide solvent blank by using HTSD.

two important goals: (1) it removes the signal present for the solvent, which occurs just following the start of the analysis near the determination of any light end material present; and (2) the column bleed is compensated. The assumption during this process is that the solvent blank and the column bleed profiles are constant during the calibration and sample analysis. It is the HTSD operator's duty to verify this criteria for statistically meaningful results.

4.3 Calibration

The HTSD calibration involves the analysis of (1) *n*-alkane calibration reference (hydrogenated polyolefin wax, polywax 655 which covers the boiling range $C_5 - C_{120}$) as shown in Figure 3, and (2) a reference oil that has been physically distilled by methods ASTM D2892 and D5236, as shown in Figure 4.

The polywax is used to calibrate chromatography elution times of the hydrocarbon components to the AEBP of the paraffin. The physically distilled reference oil is used as an external standard to calibrate the chromatography system for all sample percent recovery calculations. In addition, the HTSD analysis results found for the reference oil are compared to the mass distribution data known from physical distillation of the reference oil, and the statistical error of the difference between HTSD data versus actual boiling point data is reported (Table 1).

4.4 Determination of Hydrocarbon Yield as a Function of Boiling Point

The HTSD analysis result gives a chromatogram of detector signal response as a function of chromatography retention time, and a tabulated report of boiling point distribution of hydrocarbon yield at specific boiling cut-points in cumulative percent mass of sample (Figure 5, and Table 2). The report shows percent mass of material recovered in the analysis, IBP, FBP, and whether material boiling at higher than 732 °C (1350 °F) is present. The IBP is the temperature (corresponding to the retention time) at which a cumulative yield is equal to 0.5% of the total sample. The FBP is the temperature (corresponding to the retention time) at which a cumulative yield is equal to 99.5% of the total sample. The HTSD result can also be expressed in a carbon number distribution format which gives a graphical plot and tabulated report of yield at each *n*-alkane carbon number in incremental and cumulative percent mass (Figure 6).

of HTSD and statistically meaningful results. The QC includes the initial analysis for calibration of the reference oil that has been physically distilled by methods ASTM D2892 and D5236. As discussed in section 4.3 above, the HTSD yield with boiling point results for the reference oil are compared to the physical distillation mass distribution data, and the statistical error of the difference between HTSD data and the data by physical distillation is calculated and compared with acceptance limits established for the HTSD method.

Figure 6 *n*-Alkane carbon number distribution from HTSD analysis of Gulf of Mexico crude oil sample.

Statistical analysis of QC samples is done with materials such as:

- a blend of physically distilled gas oils,
- lube feed stocks,
- hydrotreated residue,
- crude oils of different specific gravity (for example, California crudes and Gulf of Mexico crudes).

For each (QC) sample, the mean and standard deviation (SD) of the temperature vs percent yield is tracked over time. Using an X-type control chart, any excursions beyond ±2 or 3 SD limits will signal an out of control range method (Figures 7 and 8). Appropriate maintenance and corrective action is triggered before a sample analysis is reported.

Figure 7 QC X-chart for full range (naphtha and residue-containing) sample (% off at 360 °F) by using HTSD.

Figure 8 QC X-chart for full range (naphtha and residue-containing) sample (% off at 1000 °F or pitch yield) by using HTSD.

5.2 Instrument Performance and Maintenance

Careful operator evaluation of the system performance is a condition for accurate HTSD data. Visual inspection of the *n*-alkane calibration reference is useful in evaluating system performance. Chromatographic peak shape symmetry of the *n*-alkanes and changes in their retention times can give an indication of the condition of the chromatography column and also the GC injector liner. The solvent blank analysis is also important in monitoring any shifts in baseline during the analysis.

Performance is affected by variables such as loss of the stationary phase at high temperatures (i.e. resulting in loss of film thickness and sample capacity) and the unavoidable build-up from residue containing samples of nonvolatile materials, such as metals, and asphaltenes in the injector and the column. Corrective action often involves replacing the GC injector liner, cutting off a short length of the column at the inlet, or replacing the column with a new one.

5.3 Interlaboratory "Round-robin" Test Results

Since HTSD is currently under ASTM proposed method status, methodologies that are followed in conducting this analysis vary. Users of the technique generally follow a manufacturer's recommended practices for their particular instrumentation. Interlaboratory "round-robin" testing of HTSD draft methods and ruggedness studies for reproducibility are under investigation by ASTM Committee D-2 Study Group and internally by petroleum refining companies that use the technique. The data in Table 3 (provided by Royal Dutch/Shell Laboratories) show interlaboratory round-robin results for five different crude oils by six laboratories. The percent mass of hydrocarbon yield with temperature are given for each crude type and laboratory. Statistical analysis of the data shows the averages, SDs, relative SDs, and the overall average SDs for the HTSD analyses. As shown, precision is best at the cut point yields of 20%, 50%, and 70%, and is lower near the beginning and end cut points of 10% and 90%. The relative SDs of the total percent recoveries of material in the range $<720\,^{\circ}C$ (corresponding to the boiling point of *n*-alkane C_{100}) ranged from about 1% to 5% for the different crude oils tested.

6 PETROLEUM REFINING APPLICATIONS

Distillation is the primary separation process used in crude-oil refining. Although the refinery unit has some nonideality that is not seen in laboratory-scale distillation, laboratory distillation is valuable in simulating the actual plant process. Laboratory analysis data on refinery process streams are often relied on as part of evaluation of unit performance. Process improvement and optimization decisions can be made with the help of laboratory test results that relate to plant occurrences.

6.1 Atmospheric Crude Distillates

Most atmospheric crude units produce atmospheric gas oil (AGO) product for hydrocracker or fluidized catalytic cracker (FCC) feed. A well-designed and proper operating unit will produce AGO with only barely detectable levels of metals present. Generally no volatile metals are found in AGO. Some units, however, produce AGO with relatively high levels of undesirable metals, such as

30 ppm mass nickel plus vanadium caused from entrained residue.[12] An example of estimating an entrainment level is to fractionate AGO by ASTM D5236 into two cuts containing the first 95 volume percent and final 5 volume percent. HTSD results, along with results from metals analysis methods, can then be used to help quantify the residue entrainment.

6.2 Crude Vacuum Distillates

Crude vacuum column units produce heavy distillate for downstream processing in an FCC or hydrotreater. Knowing the feedstock distillation curve slope and incremental gas oil contaminants is valuable for optimizing production of heavy vacuum gas oil (HVGO). Understanding contaminant distribution and HVGO product quality is important. For many crudes, high amounts of volatile metals and residue can lead to downstream catalyst poisoning. Laboratory analysis data is important for measuring HVGO yields and quality at different cut points and to determine feedstock contaminant distributions for predictive design work. Distillation curve data for vacuum column feedstocks are obtained in the laboratory by using various distillation techniques such as column distillation, short-path distillation, and SimDist by GC.[12] Column distillation includes spinning-band distillation, batch distillation (ASTM D5236), and continuous-flash vaporization. Physical distillation methods result in overlap between cuts and resultant inaccuracy in the contaminant distribution curve. HTSD analysis of each cut allows the contaminant curve to be corrected for overlap. An example of this application of HTSD is shown in Figure 9. In another example as shown in Figure 10, HTSD was used

Figure 9 Analysis to characterize refinery vacuum tower products by using HTSD.

Figure 10 Analysis to characterize preparative physical distillation cuts by using HTSD.

to characterize seven laboratory preparative high vacuum distillation fractions at 25 °F cut points. The HTSD result can determine both the median boiling point of each fraction and also the preparative distillation efficiency or dispersion. With the boiling range of the preparative fraction precisely defined by HTSD and data concerning the properties, obtained by conducting other analyses on the preparative fractions such as density, asphaltenes, Conrad Carbon, and metals, useful vacuum tower optimization models for specific feeds and specific catalyst poisons can be developed.

6.3 Resid Processing Characterization

Crude oil bottoms present challenges to refiners who need to effectively convert them into useful products. Among the many ''bottom of the barrel'' processes available, solvent deasphalting is predominantly used to recover high-value deasphalted gas oil (DAO) from petroleum resid. DAO is excellent feedstock for lube oil, fluid catalytic cracking, and hydrocracking. The residuum oil supercritical extraction (ROSE™) process licensed by Kellogg Brown & Root is a state-of-the-art solvent extraction process widely used in the industry today.[13] HTSD is a useful tool for characterizing hydrocarbons by using boiling point profiles of fractions from the resid solvent extraction process.

The HTSD data presented in Figure 11 and in Table 4 show the chromatograms and percent mass yield as a function of boiling point for sample fractions from a ROSE™ process.[14] In this study, propane was used to extract the deasphalted oil fraction from the petroleum residue.

HTSD has proven valuable for characterizing yield at defined temperatures for heavy feeds and products in the development of technology for upgrading crude and heavy oils. For example, the chromatograms shown

Figure 11 Analysis for resid (a), DAO (b), and asphaltene (c) from the ROSE™ process by using HTSD.

Table 4 HTSD yield (% weight) as a function of boiling point for fractions from the (ROSE™) process

in Figure 12 along with the data in Table 5 illustrate HTSD results for process feed and product samples from the FLEXCOR T process. This is a proprietary Exxon process to upgrade crude and heavy oils with a high naphthenic acid (i.e. total acid number (TAN)) content. The process reduces TAN (reportedly by about 90%) and as a result reduces the corrosivity of crudes and heavy oils caused by TAN in downstream refineries. The process provides moderate resid conversion under low severity operating conditions. While HTSD for this application is not for detection or measurement of TAN removal, HTSD is valuable for characterizing the reduction in the

Figure 12 Analysis for feed (a) and product (b) from the Exxon FLEXCOR T process by using HTSD.

amount of resid and the increase of liquid yield at defined temperatures.

7 CRUDE OIL CHARACTERIZATION

7.1 Yield Correlations between Crude Assay Distillation and High-temperature Simulated Distillation

The crude assay distillation procedure is defined by the methodologies of ASTM Methods D2892 and D5236. The procedure first uses a 15-plate column operating under a reflux ratio of 5 : 1 (D2892) which, as discussed in section 3.1, is known as TBP distillation. The distillation is usually started at ambient pressure (760 mmHg)

and then switched to vacuum conditions (for example, from 100 mmHg and then to 2 mmHg minimum) to extend the method to about 343 °C (650 °F) AEBP. At this point the remaining charge is transferred to a vacuum potstill method (D5236) where the distillation is continued at lower pressure (0.3 and 0.1 mmHg minimum allowed) thus allowing for an AEBP limit of about 538–565 °C (1000–1050 °F). Conversion tables for the vacuum conditions to AEBP are included in the methods.

Although the crude assay distillation (D2892 and D5236) procedure provides only an estimate of the yields of the products of various boiling ranges, the results (when properly and skillfully obtained) are of great importance for the characterization and commercial trading of crudes. However, several areas that can contribute to data variability of the crude assay distillation procedure include:

- the use of two different consecutive distillation methods with widely different characteristics such as efficiency, column hold-up and pressure drop across the column;
- inaccuracies in pressure and temperature readings and the subsequent conversion to AEBP;
- maximum attainable temperatures (AEBP) and cracking limits (maximum liquid temperature tolerance) are different for different types of crudes.

This grouping represented a good range of crudes with widely varying content of pitch, sulfur, nickel, vanadium, oxygen, Conradison Carbon or microcarbon residue, and asphaltene.

The comparisons of the yield curves (expressed in mass percent) of crude assay (ASTM D2892 and D5236) to HTSD were presented for five typical crudes spanning the range of light, intermediate, and heavy API gravities. Each crude was compared at eleven distillation cutpoints (°F): 68, 155, 265, 350, 400, 500, 600, 700, 800, 900, 1000. In another series of comparisons, the percent mass at each of the eleven cutpoints as determined by HTSD was subtracted from the percent mass from crude assay (D2892 and D5236).

The HTSD analysis results of crudes have been compared to crude assay distillation results in a study reported by Villalanti et al.[15] About 100 crudes ranging in API gravity from light to heavy were analyzed. In that study the crudes were grouped into three categories (Table 6) based on API gravity. API gravity is a function of relative density (specific gravity) that is widely used in the petroleum industry. The API value [(141.5/specific gravity 60/60 °F) −131.5 min] requires no statement temperature because it is included in the definition of the measurement; API gravity values decrease as density increases and range from 0 (equivalent to density 1.076) to 100 (equivalent to density 0.6112).

Table 6 Crude type, based on API gravity

Crude type	API gravity	Number of crudes	API range
Light	>30	49	30.1–52.3
Intermediate	20–30	27	20.5–30.0
Heavy	<20	8	9.7–19.5

Table 7 HTSD cutpoint data for a QA sample

HTSD cutpoint (°F)	% Mass	SD
360	12.7	0.3
480	19.6	0.3
650	28.9	0.3
1000	73.0	0.5
1351	98.4	0.9

The QA sample for the HTSD analysis was a full range (naphtha and residue containing) petroleum sample. The HTSD cutpoint statistics determined for the QA sample for more than 500 determinations were as given in Table 7.

The comparison of the distillation yield curves (percent mass) as determined by crude assay and by HTSD showed good agreement. In general, the difference was better than ±2% mass over the cutpoint range of IBP to 538 °C (1000 °F) (Figure 13). The only exception to this is the region around 399 °C (750 °F). The deviation in this region is caused by the change from high efficiency (15 plates) D2892 distillation to low efficiency (one plate) D5236 distillation. The distillation at this point goes from TBP distillation to non-TBP distillation. This results in a larger deviation for HTSD versus physical distillation at the crossover and beyond, and also introduces a bias between D2892 and D5236 (Figures 13 and 14). The fact that HTSD has no crossover effects is one of its main advantages for modelling and monitoring purposes.

The SD of HTSD at cutpoints up to 538 °C (1000 °F) is better than 0.5%. The estimated precision of the

Figure 13 Comparison of physical distillation assay and HTSD as % weight difference in their values at each cut point for crude oils grouped by API gravities.

Figure 14 Comparison of physical distillation assay and HTSD as the SD of the difference of their values at each cut point for crude oils grouped by API gravities.

correlation between crude assay distillation and HTSD yield at each cutpoint results in an SD of <2% weight except at the crossover point at 399 °C (750 °F) (Figure 14).

Advantages cited in that study for characterization of crude by HTSD include:

- method precision;
- faster turnaround and less expense than laboratory physical distillation;
- valuable business tool for evaluating new crudes and confirming crude quality before purchase;
- ensuring crude product integrity during transportation and delivery.

7.2 Crude Oil Contaminants

Product integrity must be verified in the course of crude oil trading. Enormous quantities of crude oil are transported and processed daily. Product adulteration can occur whether intentionally or not. A useful application of HTSD is in monitoring product integrity. For example, the blending of pitch (defined as 538 °C+ or 1000 °F+) into crudes has been spotted at concentration levels of about 1.5 percent mass and lower.[16] Advantages of HTSD for this application include speed of analysis, small sample quantity requirement, and extended boiling range of the method.

8 PETROLEUM HYDROCARBONS IN ENVIRONMENTAL SAMPLES

SimDist methods are becoming more widely used in environmental applications. HTSD is useful for characterizing hydrocarbons which can be present as soil and water contaminants; for example, to map and follow hydrocarbon removal processes which may involve biodegradation, thermal, and/or physical separation methods.

Figure 15 Analysis of environmental soil sample extract by using HTSD.

8.1 Soil Contaminants

An example of a soil extract analysis by HTSD is shown in Figure 15. For analysis the soil is weighed into a small vial and contacted with a weighed amount of solvent such as carbon disulfide, and the extract is analyzed. To improve sensitivity, samples are prepared for analysis at soil to solvent ratios of about 50 percent mass. Other extraction techniques and solvents can also be used. The HTSD result is useful for characterizing the amounts of material over boiling range regions representative of naphtha, gasoline, diesel, and heavier material. The detectable hydrocarbons can be reported on the basis of percent mass of soil as received or on a normalized percent hydrocarbons.

8.2 Oily Waters

In the HTSD analysis of a predominantly aqueous matrix, the sample is weighed into a small vial and shaken with a weighed amount of solvent, such as carbon disulfide, and the extract analyzed. In this case the extract is the bottom layer because carbon disulfide is denser than water. Water to solvent ratios of about 50% mass are used. Other extraction techniques and solvents can also be used. As with soil samples, the HTSD result is useful for characterizing the amounts of petroleum hydrocarbons in the boiling range of naphtha, gasoline, diesel, and heavier material. The detectable hydrocarbons can be reported on basis of percent mass of sample as received or on a normalized percent hydrocarbon basis.

ACKNOWLEDGMENTS

The authors wish to thank the following colleagues for their valuable contributions to this article: Roby Bearden, Jr, Exxon Research and Development Laboratories,

for his discussions concerning HTSD applications in the FLEXCOR T process; Rinus Daane, Royal Dutch/Shell KSLA, for providing data on the interlaboratory round-robin studies of the HTSD analyses of crude oils; Murugesan Subramanian, Kellogg Brown & Root, for information on HTSD applications in refinery ROSE™ solvent deasphalting operations.

The analysis of hydrocarbon mixtures originating from mineral oil sources using gas chromatography (GC) is compiled in this article and a general overview of GC and detectors, including hyphenated instrumentation, is given. The advantages and limitations of GC, as well as multidimensional GC are described in more detail from a standpoint of process GC, and the historical development of chromatography is put into perspective. Comprehensive tables of target analytes and methods offer access to all standard methods published by the American Society for Testing and Materials (ASTM) for hydrocarbon analysis with GC. Based on these tables, several subtopics are covered: gaseous and liquid hydrocarbons, heteroatom analysis, comprehensive and impurity analysis, natural gases, gasoline and fuel production, polymer feedstocks, hyphenated techniques, and bulk properties.

1 INTRODUCTION

The analysis of hydrocarbons with GC is described in this article. The scope of applications is fairly narrow and covers hydrocarbons originating from mineral oil. This includes products supplied by the refining, petroleum, petrochemical, and oil industry, but not biological samples, environmental applications, food, extraterrestrial sources, etc.

1.1 Hydrocarbons

Hydrocarbons are understood as compounds consisting only of hydrogen and carbon with the general molecular formula C_xH_y. In finished petroleum products such as gasoline, it is also of interest to determine fixed gases and hydrocarbons containing sulfur or oxygen. Therefore, a few methods for the analysis of hydrocarbons with these heteroatoms are included as well.

1.2 Gas Chromatography

GC is a technique that separates gaseous mixtures into their components. In many cases, this technique can also be called gas–liquid chromatography: during the separation process, an inert gas (carrier gas, mobile phase) carries the gaseous mixture over a thin layer of an immobilized liquid (stationary phase). As mixture molecules are swept past the liquid film, they briefly permeate the surface and ''dissolve'' in the liquid before being released again into the gas stream. In essence, an equilibrium exists at any given point between the gas and liquid phase for all components; they are partitioned between the gas and liquid phases. This journey of mixture components takes place inside a tube that is either coated on the inside with a stationary phase (open tubular column), or filled with a grainy powder (support phase) that is coated with the stationary phase (packed column). A stronger affinity of a compound for the stationary phase results in a higher ''concentration'' in the liquid phase, effectively slowing the migration of this compound relative to the inert mobile phase. With an appropriately chosen stationary phase, most or all mixture constituents

Figure 1 Schematic column separation diagram. The jagged column walls symbolize ''resistance'' against mixture molecules.

exhibit different partition coefficients. Therefore, the time that these components spend inside the column (retention time) will be different, so that they successively emerge (elute) from the column as separately detectable packets (see Figure 1 for a schematic illustration of column chromatography).

GC does not only deal with mixtures that exist as gases at ambient temperatures, but also for liquid mixtures that can be evaporated at operating temperatures of a gas chromatograph. The evaporation is often carried out during the introduction of a sample onto the column (injection). Elevated temperatures inside the column compartment (oven) are used to turn most or all of the injected sample into a gas. Owing to thermally labile samples or limits of the stationary phase, most GC separations do not exceed 200–300 °C. Newer column and oven technology has extended this limit to almost 500 °C. At the other end of the temperature spectrum, subambient separations can start as low as −60 °C.

1.3 Detection

The great majority of hydrocarbon separations with GC are quantitative in nature, although preparative and qualitative GC exists as well. For the determination of separated components, suitable detectors are employed, mostly universal detectors such as thermoconductivity detectors (TCD) or flame ionization detectors (FID). A TCD is a nondestructive detector suitable for quantitating components in a concentration range of approximately 0.01–100%, while FIDs operate best from the mid parts per billion (ppb, 10^{-9}) to high parts per million (ppm, 10^{-6}) range. FIDs exhibit the highest sensitivity for easily combustible compounds such as hydrocarbons. More specialized detectors for sulfur and oxygen as well as multichannel detectors will be introduced in sections 3.6 and 5.1. The continuous monitoring of the column output (effluent) with a detector yields a chromatogram which indicates the separated mixture constituent packets (eluents) as peaks (see bottom of Figure 1).

Sometimes, GC is also used to determine bulk properties such as boiling point distribution or vapor pressure instead of separating individual mixture constituents. In these cases, a chromatogram is evaluated as a whole and the mixture does not have to be separated into individually quantifiable peaks (see section 5.2).

1.4 Advantages

GC instrumentation is robust and a large body of literature and knowledge exists.[1–6] It is well suited for volatile samples whose constituents can be evaporated at temperatures up to 300 °C (sometimes even 450 °C). Compared with other instruments, the capital and maintenance costs are low. Using appropriate columns and methods, GC can be highly selective in detecting and determining a wide range of analytes. When hyphenated with multichannel detectors (see section 5.1), GC is used not only for quantitative, but also for qualitative analyses.

1.5 Limitations

Not many sample matrices are suitable for direct (neat) introduction into a GC. Sample cleanup is often required and aqueous samples or salts are frequently detrimental to a GC's hardware. GC also may not be suitable for the analysis of thermally labile samples. In addition, analytes must be in the gas phase during a split/splitless sample injection and the temperature profile of a separation must be designed to put all analytes into the gas phase. With complex samples, complete separation of all target analytes may require substantial hardware and method development investments, if it can be achieved at all. Potential interferences are difficult to detect if they overlap (co-elute) with the analytes of interest, a problem that can be overcome with multichannel detectors (see section 5.1). Carrier gas must be supplied continuously, which may sometimes be difficult with the most commonly used carrier gases helium (expensive in many parts of the world) and hydrogen (explosion hazards). Duty cycles (times between repeated measurements) for even moderately complex separations (5 min to more than 2 h) may be too long for quick responses based on GC analysis results.

Table 1 Process analysis approaches. (Adapted from McLennan[10])

Type	Advantages	Disadvantages
Off-line	Expert analysts available Flexible operation Controlled environment Sophisticated instrumentation Low unit costs per test	Slow Lack of ownership of data Conflicts of priorities Additional administration costs
At-line	Dedicated instrument Faster sampling process Simpler instrumentation Ownership of data by production Control of priorities	Low equipment utilization Robust equipment necessary
On-line	Fast Automatic feedback possible Dedicated instrumentation	Downtime must be minimized Long or expensive method development 24-h maintenance resource availability Electrical classification required

1.6 Process Gas Chromatography

GC-based hydrocarbon analyses[7–9] are usually carried out in the refining, petroleum, and petrochemical industry, where the majority of GCs are used to provide information about the production process. This can be done in an ''off-line'', ''at-line'', or ''on-line'' fashion. Table 1 outlines the differences between these approaches.[10] The focus on process applications in hydrocarbon analysis with GCs is also reflected in this article, but many methods developed for on-line analysis can also be applied in the laboratory, and vice versa.

Process gas chromatography (PGC) applications[11–13] can usually be classified into either control, mass balance, or monitoring categories.[14] Control applications usually target a few key components from a single sample stream, require short duty cycles, and the analysis results are used to adjust production parameters. Mass balance applications measure most of the individual components, group the remaining ones, and provide a track record for product quality, content, and process efficiency, e.g. in the determination of the heat value of pipeline gas, which is usually expressed in British thermal units (BTUs; 1 BTU = 1.055 kJ). Monitoring applications are normally designed to meet regulatory requirements, and may obtain samples from a large number of sampling points.

2 HISTORY

The earliest chromatography experiments of Runge, Schönbein, and Goppelsröder[15] go back to the nineteenth century. However, the invention of column chromatography[16,17] is attributed to Mikhail S. Tswett, who first demonstrated it in 1903,[18–20] when he successfully separated green leaf pigments to study them in their pure state. In a glass column filled with crushed chalk, he separated the leaf alcohol extract into individually identifiable bands of different color. Hence the name ''chromatography'', which comes from the Greek words $\chi\rho\omega\mu\alpha$ (chroma = color) and $\gamma\rho\alpha\phi o\sigma$ (graphos = writing).

Partition chromatography[21] as we know it today, and GC[22,23] in particular, were invented by Martin and Synge in the 1940s and 1950s, ultimately garnering for them the Nobel Prize in chemistry in 1952.[24] Although all separations were initially done on packed columns, open tubular columns are used in the majority of today's applications.

At the same time GC was developed, mass spectroscopy (MS) began to catch on as a valuable tool for analytical chemists in the early 1950s. The natural fit between these two instruments was discovered soon after that,[25] and the ''hyphenation'' of MS as a versatile multichannel GC detector turned into today's widespread usage of gas chromatography/mass spectroscopy (GC/MS). A GC/MS instrument is often used in qualitative GC work to identify unknown mixture components, and also to quantify known constituents. (For other versatile multichannel GC detectors, see section 5.1.)

Just as in other branches of analytical instrumentation, the increasing use of computers for GC has drastically improved productivity, while also increasing the precision and accuracy of separations through hardware control and chromatogram processing. The quantification of analytes – originally done by cutting out peaks from strip-chart recorder paper and weighing them – has progressed beyond integrators with on-the-fly calculations to computers that process entire chromatograms. Computers also make it possible to calculate bulk properties, such as boiling point distribution, vapor pressure, or BTU content by analyzing complete chromatograms.

3 GENERAL METHODS

The analysis of hydrocarbons with GC covers such a vast body of methods that only a few selected applications can be described. This section deals with ''general purpose'' methods, while more specific problems and their solutions are outlined in sections 4 and 5. There are several organizations that publish standard methods for hydrocarbon analysis, namely the ASTM. The titles and designation numbers of standards published by ASTM pertaining to GC hydrocarbon applications are listed in Table 2. Other organizations for oil, gas, refining, and petroleum, or organizations that publish standards for hydrocarbon analysis with GC are listed in Table 6, and most of the standard titles are accessible and searchable via the Internet.

All ASTM standard methods in Table 2 were examined for target compounds or identified peaks in their reference chromatograms; a complete list of analytes is compiled in Table 3 and common analyte synonyms are show in Table 4. Together, these three tables provide a comprehensive ''roadmap'' to solve common hydrocarbon analysis problems. Much of the text in the following sections serves as entry points into these tables.

3.1 Multidimensional Gas Chromatography

Common chromatography obstacles such as a wide range of target analytes or long separation times are usually overcome with multidimensional gas chromatography (MDGC).[26] Possible variations for MDGC are almost limitless, but they all share common characteristics: during the separation, part of the sample is diverted from the straight *injection* → *column* → *detector* scheme to traps, vents, other columns, and other detectors. Typical applications of MDGC are multiple columns of different selectivity to cover a wider range of components, rearrangement of elution order to speed up separation, and venting of unwanted compounds to protect analytical columns or to complete a separation in less time. Comprehensive two-dimensional separation with gas chromatography (GC × GC) is another tool in the MDGC toolbox to separate mixtures with hundreds of components from a single injection.[27,28] With this technique, the effluent from a longer column is re-injected as sample pulses onto a short column, where separation is accomplished about two orders of magnitude faster than in the longer column, resulting in a three-dimensional chromatogram. As the separation in the primary and certainly in the secondary column becomes faster, narrow injection plugs, rapid sample transfer between columns, and miniaturized hardware become more and more critical.[29,30]

An example of a heartcut and backflush-to-vent MDGC system is shown in Figure 2 and Figure 3.[14] Figure 2 depicts the plumbing arrangement between valves, columns, vents, and detectors, while the flow through the columns is illustrated in Figure 3. This arrangement is used to separate trace amounts of methane and ethane from ethylene, the main constituent. Normally, these components elute in the order CH_4, C_2H_4, and C_2H_6. The separation begins with valves in position 1, stabilizing the flows prior to sample introduction. After the injection with the sample valve (SV), the valves are changed to position 2 (beginning of first heartcut), allowing the methane peak to pass from column 1 through the TCD into column 2. Once the end of the methane peak has been observed with the TCD, the valves are switched back to position 1 (end of first heartcut), which vents the ethylene peak after it emerges from column 1 and the TCD. Once the ethylene elution from column 1 is complete, the valves are switched to position 2 (beginning of second heartcut) to allow ethane (with traces of unseparated ethylene) to flow into column 2 for detection by the FID. Once ethane has completely exited column 1 (end of second heartcut), the valves are switched to position 3, reversing the flow through column 1 and thereby venting all heavier components (backflush to vent), while ethane completes its course through column 2.

3.2 Gaseous Hydrocarbons

Hydrocarbons and related gases that are in their gaseous state at ambient temperature (C_1 through C_4 or C_5) are measured in ASTM standard methods D2504 and D3612 (see also D1945, D1946, D2163, D2426, D2427, D2505, D2593, D2712, and D4424). Measurements in these methods often include fixed gases such as oxygen, nitrogen, and carbon dioxide as well, and are usually applied to natural gas processing or polymer precursor production such as ethylene or propylene.

3.3 Liquid Hydrocarbons

Except for waxes and tars of high molecular weight, most other common hydrocarbons up to about C_{20} exist as liquids at ambient temperature. The melting and boiling points of *n*-alkanes[31] are plotted in Figure 4 as reference points. Most ASTM standard methods for liquid hydrocarbon analysis with GC deal with specific applications or target compounds, but there are also several that are of general nature and do not fit into any specific category: D2306, D2597, D3524, D3525, and D5917.

3.4 Impurity Analysis

The characterization of trace components in the production of high purity compounds or in hydrocarbon waste is important to meet customer specifications, avoid catalyst poisoning in polymer production, or to comply

Table 4 Common synonyms for analytes listed in Table 3

Synonym	Name used in Table 3	Synonym	Name used in Table 3
Allene	Propadiene	iC4	2-Methylpropane
Amylene	2-Methyl-2-butene	iC5	2-Methylbutane
Butadiene dimer	4-Vinyl-1-cyclohexene	Isobutane	2-Methylpropane
2-Butanethiol	1-Methyl-1-propanethiol	Isobutanethiol	2-Methyl-1-propanethiol
s-Butanethiol	1-Methyl-1-propanethiol	Isobutanol	2-Methyl-1-propanol
t-Butanethiol	2-Methyl-2-propanethiol	Isobutene	2-Methylpropene
s-Butanol	2-Butanol	Isobutyl alcohol	2-Methyl-1-propanol
t-Butanol	2-Methyl-2-propanol	Isobutylene	2-Methylpropene
Butyl alcohol	1-Butanol	Isobutyl mercaptan	2-Methyl-1-propanethiol
s-Butyl alcohol	2-Butanol	Isodurene	1,2,3,5-Tetramethylbenzene
t-Butyl alcohol	2-Methyl-2-propanol	Isoheptane	2-Methylhexane
s-Butylbenzene	2-Phenylbutane	Isohexane	2-Methylpentane
Butyl mercaptan	1-Butanethiol	Isooctane	2,2,4-Trimethylpentane
s-Butyl mercaptan	1-Methyl-1-propanethiol	Isopentane	2-Methylbutane
t-Butyl mercaptan	2-Methyl-2-propanethiol	Isopropanethiol	2-Propanethiol
Butyl methyl ketone	2-Hexanone	Isopropanol	2-Propanol
C1	Methane	Isopropenylbenzene	α-Methylstyrene
C2	Ethane	Isopropyl alcohol	2-Propanol
C2=	Ethylene	Isopropylether	Diisopropylether
C3	*n*-Propane	Isopropyl mercaptan	2-Propanethiol
C3=	Propene	Mesitylene	1,3,5-Trimethylbenzene
C4	*n*-Butane	Methyl acetylene	Propyne
Carbon oxysulfide	Carbonyl sulfide	Methyl alcohol	Methanol
Crotonylene	2-Butyne	Methylbenzene	Toluene
Cumene	Isopropylbenzene	Methyl disulfide	Dimethyl disulfide
trans-Decahydronaphthalene	*trans*-Decalin	(1-Methylethenyl)-benzene	α-Methylstyrene
Diisobutylene	2,4,4-Trimethyl-1-pentene	(1-Methylethyl)-benzene	Isopropylbenzene
Diisopropyl	2,3-Dimethylbutane	Methylethylketone	2-Butanone
Dimethyl acetylene	2-Butyne	Methyl ethyl sulfide	Ethyl methyl sulfide
1,2-Dimethylbenzene	*o*-Xylene	Methylketone	Acetone
1,3-Dimethylbenzene	*m*-Xylene	Methyl mercaptan	Methanethiol
1,4-Dimethylbenzene	*p*-Xylene	Methyl sulfide	Dimethyl sulfide
Dimethylketone	Acetone	Monoglyme	1,2-Dimethoxyethane
1,1-Dimethylpropyl methyl ether	*t*-Amyl methyl ether	MTBE	Methyl *t*-butyl ether
1,1-Dineopentylethylene	4,4-Dimethyl-2-neopentyl-1-pentene	nC4	*n*-Butane

Table 4 (*continued*)

Synonym	Name used in Table 3	Synonym	Name used in Table 3
DIPE	Diisopropylether	nC5	*n*-Pentane
Durene	1,2,4,5-Tetramethylbenzene	Neohexane	2,2-Dimethylbutane
ETBE	Ethyl *t*-butyl ether	Neopentane	2,2-Dimethylpropane
Ethene	Ethylene	*t*-Pentanol	2,2-Dimethyl-1-propanol
Ethyl acetylene	1-Butyne	Phenyl sulfide	Diphenyl sulfide
Ethyl alcohol	Ethanol	2-Propanone	Acetone
Ethyl disulfide	Diethyl disulfide	Propyl alcohol	1-Propanol
Ethylene glycol dimethyl ether	1,2-Dimethoxyethane	Propylene	Propene
Ethyl mercaptan	Ethanethiol	Propyl mercaptan	1-Propanethiol
Ethyl sulfide	Diethyl sulfide	Pseudocumene	1,2,4-Trimethylbenzene
2-Ethyltoluene	1-Methyl-2-ethylbenzene	TAME	*t*-Amyl methyl ether

Figure 2 Plumbing diagram for heartcut and backflush-to-vent arrangement. HC = heartcut, BF = backflush, CV = column valve. (Adapted from Combs and Cook, Figure 4.22.[14] Copyright 1995, Chapman & Hall. Reprinted with kind permission from Kluwer Academic Publishers.)

with environmental regulations. ASTM methods D2360, D3054, D3760, D3797, D3798, D4291, D4735, D5060, and D6229 address impurity analyses of a more general scope. (Methods D2268, D2426, D2505, D2593, D2712, D4492, D4864, D5135, D5441, and D5713 are geared more towards specific applications.)

3.5 Comprehensive Analysis

An encompassing analysis of naturally occurring hydrocarbon mixtures and derived products is almost impossible, considering that these mixtures contain hundreds, if not thousands, of closely related compounds. The number of possible isomers for saturated alkanes with the general molecular formula C_xH_{2x+2} expands rapidly as the carbon number increases.[32] Between C_1 and C_6, there are 13 different isomers, but between C_7 and C_{12}, this number increases to 651. This does not even take cycloalkanes, olefins, and aromatics into account. A few ASTM methods specialize in analyzing a section of the hydrocarbon spectrum, identifying many of the components in complex mixtures: D5134, D5442, and D5443.

3.6 Heteroatom Analysis

During the production of petroleum products, it is frequently necessary to remove sulfur-containing components to minimize the sulfur content of the process output. This in turn reduces the generation of SO_2 during the combustion of fuels consumed for propulsion, heating, and energy production in power plants. Sulfur is also undesirable in the production of polymers from

Figure 3 Valve operation diagrams. (Adapted from Combs and Cook[14] Figure 4.23, Copyright 1995, Chapman & Hall. Reprinted with kind permission from Kluwer Academic Publishers.)

Figure 4 Melting points ( ) and boiling points (◇) for straight chain alkanes from C_4 through C_{32}.

olefins, because it renders many polymerization catalysts useless. In GC methods, sulfur-containing components are frequently detected with a flame photometric detector (FPD) or a pulsed flame photometric detector (PFPD). In these methods, a complete separation from other hydrocarbons is necessary to avoid a loss of the sulfur signal (quenching). This problem and the nonlinear response of FPDs are circumvented with the sulfur chemiluminescence detector (SCD), which is used in ASTM method D5623.

In order to meet governmental emission regulations without compromising driveability, today's gasoline blends usually contain specific amounts of oxygen-containing compounds such as ethers or alcohols. The concentration of these ''oxygenate'' additives does not reach trace levels, so they are normally analyzed with general-purpose detectors (FID, TCD). However, for oxygen-specific detection, an oxygen-selective flame ionization detector (OFID) can be used, and ASTM method D5599 takes advantage of this technology.

Other ASTM methods that target oxygen- or sulfur-containing compounds are D5008, D5303, D5504, D5541, and D6228 (see also D4735, D4806, D4815, D5441, and D5501).

3.7 Specific Compounds

ASTM offers a number of methods that deal with the analysis of specific nontrace target analytes, usually for purity analysis: D2268, D3257, D3606, D4367, D4492, D5135, D5501, D5713, and D5441 (see also D3054, D3760, D3797, D3798, D4291, D4735, D5008, and D5060).

4 ON-LINE APPLICATIONS

A number of hydrocarbon analysis problems are typical applications for PGCs and some of them are outlined in this section. The main differences between laboratory (off-line) and process (on-line) GCs are outlined in Table 1. In addition, PGCs are calibrated almost always externally owing to the difficulty of mixing internal standards into a process stream.

4.1 Natural Gas Analysis

In most cases, the analysis of natural gas with GC is straightforward, including ''fixed gases'' such as H_2, He, N_2, O_2, CO, and CO_2, which can be detected with a TCD using hydrogen or helium carrier gases. If H_2 and He need to be detected, a nitrogen carrier gas is generally used. ASTM methods D1945, D1946, and D2163 (see also D6228) describe the analysis of natural gases. In some cases, CO or CO_2 may have to be measured at trace levels, where FID detectors are usually employed, but neither of these two analytes can be detected directly with an FID. In order to overcome this limitation, these two components are passed through a methanator that converts them to CH_4, which in turn is easily detectable by an FID.

4.2 Gasoline Blending

Gasoline and other propulsion fuels have to bridge several goals, which sometimes seem to conflict with each other: environmental regulations, which vary from country to country and even from state to state, fuel evaporation rates based on seasonal temperatures, driveability (octane number), consumer prices, compatibility with combustion engines manufactured throughout the twentieth century, different fuel grades, and more. Several parameters such as Reid vapor pressure (RVP), total aromatics, total sulfur, total oxygenates, and total olefins are measured to control and adjust the production process,[33] and a couple of ASTM methods assist in characterizing finished fuel products to ensure consistent quality: D2427, D4420, D4806, D4815, D5580, and D6296. There are also a number of other ASTM methods that are not necessarily fuel specific, but may also be needed to analyze additives that are used during the gasoline blending process: D3606, D5441, D5501, D5504, D5541, D5599, D5623, D5769, and D5986.

4.3 Polymer Production Feedstock

A very significant portion of polymer products are manufactured using ethylene, propylene, and other olefin precursors. In most cases, these olefins must meet certain purity standards in order to be usable for polymer production. For example, ''polymer grade'' ethylene must be >99.9% pure, and typical trace impurities are methane and ethane ($CH_4 + C_2H_6 < 0.15\%$), acetylene (<5 ppm), and CO_2 (<10 ppm).[34] ASTM methods that analyze impurities in ethylene, propylene, and butadiene are D2426, D2505, D2593, D2712, D4424, D4864 (see also D2163 and D5303).

5 OFF-LINE APPLICATIONS

Most on-line applications can also be employed in off-line analyses, and vice versa, but the two application areas outlined below are usually done in a laboratory setting.

5.1 Hyphenated Techniques

Many of the previously discussed GC detectors (TCD, FID, SCD) are single-channel detectors, which means that they provide a single signal for each measured point along a chromatogram. Their simplicity can also lead to problems, when target analyte peaks overlap or merge with interferences, or when unknown components need to be identified. Single-channel detector responses cannot discriminate between closely eluting analytes, and identification based on retention time is risky at best. This problem is usually solved by linking or ''hyphenating'' GC instruments with general-purpose instruments such as mass spectrometers, which provide an entire spectrum for each measured point along a chromatogram.[35] Most compounds give rise to different mass spectra, so that a computer-based separation of overlapped components[36] or the identification of unknown components becomes possible.

One of the shortcomings of MS, the inability to distinguish between isomers, was recognized as well. Infrared spectroscopy (IRS) overcomes this problem, but it took much longer to develop a practical interface between IRS and GC.[37] Compared with GC/MS, gas chromatography/infrared spectroscopy (GC/IRS) is much less used today because of higher instrumentation cost, lower reliability, and lower sensitivity.[38] This is particularly true for hydrocarbon analysis with GC/IRS. In rare cases, when the analysis of organometallic compounds is necessary, atomic emission spectroscopy (AES) can also be used as a GC detector for general hydrocarbon analysis.[39,40]

There are many applications for GC/MS[41,42] and most GC laboratories, if not all of them, use MS in at least one of their GC instruments to maximize the versatility of their analytical capabilities. ASTM defines only one GC/MS method, D5769, for the analysis of finished gasoline. For GC/IRS as a much less widely applied technique, ASTM offers a standard method as well. The GC/IRS method D5986 expands the scope of the GC/MS method D5769 in order to distinguish between isomers such as dimethyl- and trimethylbenzenes.

5.2 Bulk Properties

Chromatograms contain a host of information pertaining not only to the concentration of the sample constituents, but also to so-called ''bulk properties'' that are not tied to any particular compound, but to the entire mixture. Such properties include BTU values, specific gravity, vapor-to-liquid ratio (V/L), RVP, carbon numbers, and boiling point distribution. In particular, the determination of boiling point distributions with GC (simulated distillation) is of interest in many areas of the petroleum processing industry,[43] because it avoids costly, time-consuming, and error-prone analyses with actual distillation equipment. Simulated distillation with GC is actually quite simple: the system is calibrated with a mixture of hydrocarbons of known boiling points, typically *n*-alkanes, and several representative aromatics and branched alkanes. During a temperature-programmed separation, the components of the calibration mixture elute at known times and therefore calibrate the time axis as a ''temperature axis''. When an actual sample is analyzed, the total chromatogram area is calculated, and then the first *n*% of this area are correlated to the temperature axis to

obtain ''temperature versus percent off'' value pairs. ASTM defines several methods for simulated distillation (D2887, D3710, D5307, D5399, and D5480), which have to operate within certain temperature and sample constraints.

ACKNOWLEDGMENTS

I wish to acknowledge Ulrich Gökeler (Siemens AG) and Christopher Schalleur (Honeywell Industrial Automation) for providing me with application notes for systems manufactured by their respective companies. I also wish to thank Bob Bade and Jerry Combs for providing valuable input during the writing of this article.

For reference purposes, major vendors of PGCs are listed in Table 5, and most of them provide some information about their gas chromatographs that go beyond mere advertising. Aside from ASTM, many organizations provide standards or application notes for GC hydrocarbon analysis, and many of them are accessible or searchable on the Internet as well (see Table 6).

ABBREVIATIONS AND ACRONYMS

Base oils used in the formulation of lubricant products are a complex mixture of paraffinic (prevalently branched), aromatic and naphthenic (cycloparaffinic) molecules ranging in carbon number from 20 to 40+. Most automotive crankcase oils, accessory fluids, and many industrial lubricants contain in excess of 80% base oil in their "finished" formulation.

The compositional analysis of Lube base oils is usually obtained by a two-step procedure. The first step separates the aromatic and saturated fractions by column chromatography (American Society for Testing and Materials, ASTM D2549). The aromatic fraction is then further characterized by mass spectrometry (ASTM D3239) and the saturated subclasses of paraffins and cycloparaffins are measured by a different mass spectrometry method (ASTM D2786).

Recently the Lube base oils have been characterized at the molecular level by means of nuclear magnetic resonance (NMR) spectroscopy. The conventional NMR spectra have the problem of signal overlap due to the presence of a great number of isomers in the base oil composition.

To overcome the problem of signal overlap, some selected multiplet subspectral carbon-13 nuclear magnetic resonance (^{13}C-NMR) analyses were developed and, in particular, gated spin echo (GASPE) and distortionless enhancement by polarization transfer (DEPT) have been applied to obtain quantitative CH_n subspectra in petroleum fractions.

Usually the quantitative data obtained from GASPE have a better accuracy than those from DEPT and it will be shown how GASPE is applied to study the molecular characteristics of the aliphatic moieties of base oils of a different nature.

On the basis of the GASPE data and of the average molecular mass obtained via vapor pressure osmometry (VPO), the average number of branches and aliphatic rings can be calculated. Moreover, on the basis of GASPE, the distribution of side chain lengths and the positions of the methyl groups along the straight chain (methyls are the only groups for which the positions are directly obtained from NMR spectra) were obtained.

All these structural features are related to the finished lubricant's performance in both crankcase and industrial applications.

1 INTRODUCTION

Substances in all states of matter can be used as lubricants provided that they reduce friction and wear between materials in contact.

The majority of lubricants are liquids. They can be classified according to their origin into two main groups: mineral oils derived from petroleum (the majority); and synthetic oils. Most liquid lubricants contain additives to improve their natural properties, or give new properties to them, so they have qualities suitable for their applications and their efficiency may be prolonged.

Mineral lubricating oils are obtained from crude oils: the chemical composition of the crude petroleum has a great influence on obtaining lubricating oils of the required properties. In terms of chemical composition, crude oils are classified into alkanic (or paraffinic) crude oils with more than 50% alkanes, cycloalkanic or cyclic or naphthenic crude oils with more than 50% cycloalkanes, and aromatic crude oils with more than 50% aromatics. Alkanic crude oils are mostly light, wax bearing and of low sulfur content. Cycloalkanic crude oils are often heavy, wax-free or of low wax content and may contain sulfur compounds. In greater detail, the hydrocarbon groups present in the crude oils are straight-chain and branched alkanes, alkylcycloalkanes, alkylaromatics and alkylcycloaromatics.

From a property point of view, comparison of different hydrocarbon classes of the same carbon number shows that *straight-chain alkanes* (*n*-alkanes, *n*-paraffins) have the lowest viscosity, the highest viscosity index

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

(VI > 200), the lowest evaporation loss and the highest flash point. Their pour point is high (40 °C or more) and in high concentration they are undesirable. Generally they are removed from lubricating oils by solvent dewaxing or catalytic cleavage.

Branched alkanes (isoalkanes, isoparaffins) differ from the *n*-alkanes by having alkyl substituents on the main chain. If the alkyl side chains are short and not very numerous, the isoalkanes are similar to the *n*-paraffins. On the contrary, if the alkyls are long and numerous, isoalkanes have a low pour point, a relatively high VI, low volatility and evaporation loss and a high flash point. Such isoalkanes are usually present in small amounts in the conventional mineral oils, but they are predominant in the unconventional oils as those obtained by hydrocracking and hydroisomerization processes (see section 2.3) or manufactured synthetically (polyolefins).

Alkylcycloalkanes (naphthenes) of the same carbon number have higher viscosity, lower VI, lower flash point and higher evaporation loss than the alkanes and the isoalkanes, but their pour points are generally lower.

Alkylaromatics are characterized by one or more aromatic rings: aromatic rings have a greater effect than the cycloalkanic ring on the viscosity of lubricating oil cuts and at the same time decrease the VI.

2 BASE OIL MANUFACTURE

2.1 Mineral Oils

The manufacture of lubricating oils from crude oils includes separation, refining and dewaxing processes. The first step is the separation process, which is the distillation of the crude oil to produce gasoline, kerosene, gas oil and an atmospheric residue. The viscous oil cuts are obtained from the atmospheric residue by vacuum distillation. Usually the temperature does not exceed 410 °C. Vacuum distillation is normally used to produce three or four lubricating oil distillates and vacuum asphalt. Lubricating oil distillates differ from one another by distillation range, average molecular weight, viscosity, and flash and pour points. The main criteria used are the viscosity and the flash point.

The second step is the refining, which substantially changes the chemical composition of lubricating oil distillates and can thus control the properties of the distillates. Its primary effect is to reduce the concentration of the most polar constituents of the distillates. The object of this process is to improve color, the VI, and long-term stability. Nowadays the most diffuse refining process is the solvent refining, which consists of separating wax-free oil cuts into two layers: one rich in less-polar components and poor in solvent, called the raffinate layer; the other rich in polar components and solvent, called the extract layer. The most common selective solvents are furfural, which is suitable for all oil stocks, and phenol, which is used more for waxy and heavy cut oils.

The last step is the dewaxing process, which is the dominant process in the recovery of oils of low pour point and good rheological properties at low temperatures from raffinates. The oil is diluted with the solvent, chilled to low temperature and the separated wax crystals are filtered off. Suitable solvents include propane, ethane and the so-called solvent/antisolvent mixtures, such as methyl ethyl ketone (MEK).

The processes described are used for the production of base oils, which are, nowadays, regarded as conventional ones.

2.2 Hydrocracked Base Oils

Although modern types of mineral oils reinforced by additives are capable of covering a broad range of lubricating requirements, their properties are in some cases significantly surpassed by the unconventional base oils, which include hydrocracked oils, wax hydroisomerized oils and polyolefin oils. Hydrocracking of oils consists of the high-pressure hydrogenation of oils by using suitable catalysts. It enables oils to be obtained with a high VI or even an extremely high VI (up to 150). Hydrogenation changes the composition of all homogeneous oil groups: the viscosity, density, sulfur content and aromatic content are all reduced, whereas the VI, hydrogen content, concentration of cycloalkanic compounds and rings are all increased. Hydrocracking enables high-grade and high-VI oils to be produced economically. Oils of this quality cannot be obtained by solvent refining. The superiority of hydrocracked oils is in their very high VI (up to 130), good response to the additives, lower volatility at the same viscosity and lower biological activity. Less convenient characteristics are poorer stability to light, higher corrosiveness after oxidation, and lower solvent power for polar substances, which are originated by oxidation.

The hydrocracked oils are generally solvent dewaxing and, because of this, their pour points are not very low.

2.3 Hydroisomerized Base Oils

More recently, catalysts containing a hydrogenation component on a molecular sieve have been used for wax isomerization. They have permitted the development of a new process for lowering the pour points of high-wax feeds – a once-through process without requiring a solvent dewaxer – and therefore can be used to produce ultrahigh-VI oils with a low pour point. The oils obtained by this process are called wax hydroisomerized oils.

2.4 Polyolefins

The synthetic oils are the highest performance oils. They are termed synthetic because they are not obtained directly from petroleum. In comparison to mineral oil products, synthetic lubricants have the disadvantage of much higher cost. They can be classified into the following categories:

- synthetic hydrocarbons;
- polyether oils;
- esters of carboxylic acids;
- phosphoric acid esters;
- silicon-containing oils;
- halogenated hydrocarbons and halocarbons.

Among these classes of synthetic oils, we consider only the synthetic hydrocarbons because analysis of the others is not general but is specific for each product.

Synthetic hydrocarbons are produced by polymerization of olefins in the presence of Lewis acids (e.g. Al_2Cl_6, BF_3 and their complexes) or Ziegler catalyst (e.g. $Al(C_2H_5)_{3-x}Cl_x$ and promoters) in the liquid phase. They offer a number of advantages: they have narrow boiling ranges and contain small quantities of unsaturated or polycyclic aromatic compounds and traces of nitrogen-, sulfur-, or oxygen-containing impurities. They have favorable low-temperature characteristics and respond well to additive treatment. Their variable temperature characteristics are good.

In recent years, poly(α-olefins) have received considerable attention as high-performance functional fluids in a variety of applications. They are manufactured in the presence of Lewis acids by oligomerization of 1-alkenes in the range C_8–C_{12}, followed by hydrogenation of the double bond: they are almost pure isoalkanes. These poly(α-olefins) are characterized by high thermal stability, low viscosities even at low temperature, low pour points (down to $-80\,^{\circ}C$), high VI (up to 195), high flash point and low volatility. Almost all of the poly(α-olefins) available today are produced from 1-decene. They can be classified into different grades depending on their $100\,^{\circ}C$ viscosities.

3 BASE OIL PROPERTIES

Lubricants are formulated by blending base oils and additives to meet a series of performance specifications. These specifications relate to the physical properties of the oil when it is new and also ensure that the oil continues to function and protect the engine or machinery in service. Self-evidently, lubricant performance is determined by the base oils and the additives that are used in the formulation.

When selecting the appropriate base oil to use in a formulation, there are a range of properties that can be measured and used to predict performance. Although many of these properties are modified or enhanced by the use of additives, knowledge of the base oil characteristics is vital for effective formulation of any lubricant. The complexity of chemical composition of the base oils requires that most measurements are of bulk physical or chemical properties that indicate the average performance of all the molecular types in the base oil.

The main physical properties are:

- *Viscosity*. This is a measurement of the internal friction within a liquid. It is a vital property of a lubricant because it influences the ability of the oil to form a lubricating film or to minimize friction and reduce wear. The unit of absolute viscosity is the Pascal second ($Pa \cdot s$), although the centipoise (cP) is often used as an alternative unit ($1\,Pa \cdot s = 10^3$ cP).
- *Viscosity/temperature relationship – VI*. The most frequently used method to compare the variation of viscosity with temperature between different oils is by calculation of a dimensionless number, known as the VI. The higher the VI, the less the effect of temperature on the viscosity of the sample.
- *Low-temperature properties*. When a sample of oil is cooled, its viscosity increases in a predictable manner until wax crystals start to form. The matrix of wax crystals becomes sufficiently dense with further cooling to cause an apparent solidification of the oil, but it has not undergone a true phase change. Many lubricating oils have to be capable of flow at low temperatures and a number of properties should be measured. Cloud point is the temperature at which the first signs of wax formation can be detected. Pour point is the lowest temperature at which the sample of oil can be made to flow by gravity alone.
- *High-temperature properties*. The high-temperature properties of oil are governed by the distillation or boiling range characteristics of the oil. Volatility is important because it is an indication of the tendency of the oil to be lost in service by vaporization. Several methods are used to characterize volatility but the most used is the Noack method, where the sample is heated for 1 h at $250\,^{\circ}C$ and the weight loss is measured. The flash point of an oil is important from a safety point of view because it is the lowest temperature at which autoignition of the vapor occurs.

Various other physical properties may be measured, most of them relating to specialized lubricant applications.

The most important chemical property of base oils is their resistance to thermal–oxidative degradation.

Although the formulated lubricant may have many desirable properties when new, oxidation can lead to a dramatic loss of performance in service by oxidative reactions. A variety of different stability tests have been devised to measure resistance to oxidation under different conditions.

4 CHEMICAL COMPOSITION

Even if the properties of lubricating oils are largely due to the additives, the importance of the chemical composition of base oils on the finished lubricant performance is increasing more and more and this is particularly true for improved fuel efficiency, which is being driven by both legislation and product specification. This requires a deep knowledge of the molecular characteristics of the base oils, which is not easy because they consist of large numbers of structurally different compounds. A large number of correlations based on the relative distribution of paraffinic-, aromatic- and naphthenic-type hydrocarbons are reported in the literature[1–7] but these studies do not involve the nature and distribution of the aliphatic moieties, which, vice versa, determine the low-temperature and rheological properties of base stocks. Proton nuclear magnetic resonance (^{1}H-NMR) and ^{13}C-NMR techniques have been used to estimate structural parameters in petroleum cuts[8–14] but they have limitations in resolving the resonance of CH_n ($n = 0–3$) groups in the aliphatic region.

To overcome the problem of signal overlap, some selected multiplet subspectral ^{13}C-NMR analyses were developed and, in particular, GASPE has been applied to obtain quantitative abundances of CH_n groups in petroleum fractions.[15–19] Recently GASPE/NMR[20] was used to compare different base oils: mineral, hydrocracked, wax hydroisomerized, poly(α-olefins) and poly(internal olefins). From GASPE spectra the fractional abundances of CH_n, the number and length of branches, the position of methyl groups along the straight chain and the average number of aliphatic rings were obtained.

5 CONVENTIONAL BASE OIL TESTING AND ANALYSIS

The testing of lubricants is based on chemical and physical properties and on parameters that represent statistical means of the molecular properties. The essential methods have been standardized on an international basis by organizations such as the ASTM; USA, the Institute of Petroleum (IP; UK), the Deutsches Institut fur Normung (DIN; Germany) and the International Organization for Standardization (ISO). Hereafter, the most diffuse tests for analysis of physical properties and hydrocarbon type are summarized:

- *Viscosity*. Kinematic viscosity is measured routinely with ease and great precision in capillary viscometers suspended in constant-temperature baths. Standard methods are ASTM D445 and IP 71, and a number of standard temperatures are used, especially 40 °C and 100 °C.
- *Viscosity/temperature relationship – VI*. VI are calculated by measuring the kinematic viscosities of the sample at two different temperatures (40 °C, 100 °C) and comparing the viscosity change with an empirical reference scale. Full definitions of the methods of calculation are given in ASTM or IP manuals (ASTM D2270, IP 226).
- *Low-temperature properties*. The pour points are measured with ASTM D97 and IP 15, in which the oil is warmed and then cooled at a specified rate until the lowest temperature is reached at which the sample can be made to flow by gravity alone.
- *Volatility*. This is important because it is an indication of the tendency of oil to be lost in service by evaporation. Generally it is measured with the Noack method, where the sample is heated for 1 h at 250 °C and the weight loss is measured (DIN 51581).
- *Hydrocarbon analysis*. The detailed hydrocarbon analysis is obtained by a two-step procedure. The first step separates the aromatic and saturated fractions by column chromatography (ASTM D2549). The aromatic fraction is then characterized further by mass spectrometry (ASTM D3239) and the saturated subclasses of paraffins and cycloparaffins are measured by a mass spectrometry method (ASTM D2786).

6 MOLECULAR CHARACTERIZATION OF BASE OILS BY NUCLEAR MAGNETIC RESONANCE

NMR is the most important spectroscopic technique available for molecular characterization of the hydrocarbon skeleton. On the basis of the positions and intensities of signals, it is possible to identify the types and number of different nuclei, especially H and C in organic compounds. Some important books[21–23] describe the fundamentals of this spectroscopy, which is widely used in different fields such as chemistry, physics, medicine and pharmaceutics.

^{1}H- and ^{13}C-NMR techniques have been utilized also for the estimation of structural parameters of low- and higher boiling petroleum cuts. The ^{1}H-NMR spectra of

base oils consist of two main types of signal (Figure 1): a broad resonance at 6.8–8 ppm due to H on aromatic carbons; and signals at 2–0.5 ppm due to H and aliphatic carbons. In the aliphatic regions it is possible to distinguish the H of methyl groups of paraffinic chains at nearly 0.8 ppm and a sharp line at nearly 1.25 ppm due to CH_2 of paraffinic chains.

The ^{13}C-NMR spectra of base oils (Figure 2) show the signals due to aromatic carbons between 100 and 150 ppm and those of the aliphatic carbons in the region 0–50 ppm.

Particularly in the aliphatic regions there are a great number of peaks due to branched and cycloparaffins: some structural assignments have been proposed[24] but they refer predominantly to the prominent peaks, whereas

Figure 2 ^{13}C-NMR spectrum of base oil A (Table 1).

Figure 1 ^{1}H-NMR spectrum of base oil A (Table 1).

a great part of the signal is due to the multiplicity of weak resonances spread over the spectral width. The isomeric forms present originate from these latter; for instance, there are over 360 000 noncyclic alkane isomers for C_{20} alkanes and this number rapidly increases for heavier alkanes. In conventional ^{13}C-NMR spectra it is very difficult to resolve the resonances of CH_n ($n = 0$–3) in the aliphatic region.

To overcome this problem the GASPE technique has been quite useful because it allows the generation of quantitative CH_n subspectra.

An example of the application of the GASPE technique is shown in Figure 3: the ^{13}C-NMR spectrum of the squalane molecule (Figure 3), which is used as a model

Figure 3 Conventional ^{13}C-NMR (bottom) spectrum of squalane (whose molecular structure is on the top). The GASPE subspectra are labeled according to the component resonance types as CH, CH_2, and CH_3.

compound for base oil, is divided into three subspectra with the C assignments reported in the figure.

The molecule of squalane has the following CH_n groups: $(CH_3)_8(CH_2)_{12}(CH)_6$. The respective CH_n fractions according to Equation (1):

$$F(CH_n) = \frac{I(CH_n)}{\sum_n I(CH_n)} \quad (1)$$

where $I(CH_n)$ is the total intensity of the NMR signals of the CH_n group, are: $F(CH) = 0.20$; $F(CH_2) = 0.53$; $F(CH_3) = 0.27$. The $F(CH_n)$ fractions calculated from GASPE are: $F(CH) = 0.21$; $F(CH_2) = 0.53$; $F(CH_3) = 0.26$. Comparing the data obtained by GASPE with the real values, the GASPE technique results are very accurate.

We have analyzed a few different types of base oils by GASPE/NMR, and in Table 1 they are summarized using letters to define their nature. In Figure 4 the GASPE/NMR spectra of base oil L, as a general example, are shown.

Another advantage of GASPE spectra is to have the methyl signals without the presence of CH_2 signals in the region between 5 and 30 ppm. The methyl signals can be assigned to specific branching sites along the hydrocarbon chain.[25,26] An example of the methyl region of the GASPE spectrum is shown in Figure 5. The main signals of methyl groups are assigned to the hydrocarbon branches shown in Table 2.

Table 1 List of the 17 analyzed lubricating base oils

Base oil	Class[a]
A	SR
B	SR
C	SR
D	SR
E	SR
F	HISO
G	HISO
H	HISO
I	HC + HISO
L	HC
M	HC
N	HC
O	HC
P	HC
Q	PAO
R	PIO
S	PAO

[a] SR = solvent-refined mineral oils; HISO = hydroisomerized; HC = hydrocracked; PAO = poly(α-olefin); PIO = poly(internal olefin).

Figure 4 Conventional ^{13}C-NMR (bottom) spectrum of base oil F (aliphatic region). The GASPE subspectra are labeled according to the component resonance types as C, CH_2, and $CH + CH_3$.

Figure 5 GASPE CH_3 ^{13}C-NMR subspectra of base oil F as a general example.

On the basis of GASPE data, some molecular features have been calculated relating to the number of branches (*NB*) and the number of aliphatic rings (*NAR*) for an average molecule. From GASPE spectra the molar fractions of the CH_n ($n = 0$–3) aliphatic group are obtained using Equation (1). The average number of branches is estimated by multiplying the molar fraction of methyls, $F(CH_3)$, by the average number of carbons (N_C) of the base oil, obtained by VPO, which gives the average

Table 2 Methyl peak assignment of the CH_3 GASPE/^{13}C-NMR subspectrum of hydrocarbon base oil

Type of branch	δ (ppm)	Identification no.
$>CHCH_2\mathbf{CH_3}$	10.8	1
$-(CH_3)CHCH_2\mathbf{CH_3}$	11.3	2
$>CHCH_2CH_2\mathbf{CH_3}$	14.5	3
$-CH(CH_3)CH_2CH_2\mathbf{CH_3}$	14.3	4
$-(CH_2)_nCH_2CH_2CH_2\mathbf{CH_3}$	14.0	5
$-CH_2CH(\mathbf{CH_3})-CH<$	17–15	6
$-CH_2CH(\mathbf{CH_3})-CH_2-$	19.6	7
$-CH_2-CH(\mathbf{CH_3})_2$	22.6	8

number of methyls per molecule, and then subtracting two from the resulting product (the two terminal methyls of the straight chain). The expression is as shown in Equation (2):

$$NB = n\mathrm{CH_3} - 2 = F(\mathrm{CH_3})N_\mathrm{C} - 2 \quad (2)$$

The number of aliphatic rings can be calculated according to Equation (3):

$$NAR = 0.5N_\mathrm{C}[2F(\mathrm{C}) + F(\mathrm{CH}) - F(\mathrm{CH_3})] + 1 \quad (3)$$

Other molecular characteristics are obtained directly from the NMR spectra: for instance, the molar fractions of aromatic hydrogens and carbons are calculated using Equation (4):

$$F(\mathrm{H_{ar}}) = \frac{I(\mathrm{H_{ar}})}{\sum_n I(\mathrm{H}_n)} \quad F(\mathrm{C_{ar}}) = \frac{I(\mathrm{C_{ar}})}{\sum_n I(\mathrm{C}_n)} \quad (4)$$

where the denominators are the sum of all spectral intensities of the relative nuclei. In Table 3 the molecular features of the 17 base oils of Table 1 are shown, with the acronyms used in the text.

In Table 4 the molar fractions of different methyls groups with the identification numbers reported in Table 2, are shown. The hydrocarbon-type analysis of each base oil was carried out with gas chromatography/mass spectrometry (ASTM D2549, ASTM D3239 and ASTM D2786). The volume percentages of isoparaffins, cycloparaffins and aromatic compounds are reported

in Table 5, and the physical and rheological properties of the same analyzed base oils are reported in Table 6.

From the analysis of Tables 1–5 it is evident that the molecular features are peculiar to different classes of base oils. For instance, the SR mineral base oils have a greater content of aromatics (vol.% and their H and C fractions), whereas the polyolefins have a greater fraction of methyls on long aliphatic chains (identification number 6 in Table 2). These chemical features certainly influence the physical properties of the base oils: for instance, the higher value of aromatics in SR mineral oils is the cause of their higher pour points, whereas the presence of long chains in the polyolefins should be the cause of their excellent pour points. Some correlation could be tried between performance and molecular feature with statistical models, but at the moment they suffer from the limitations of the low number of significantly different base oils with respect to the large quantity of molecular characteristics shown by these complex compounds. Certainly the possibility of having predictive models of the performance of finished oils based on the molecular characteristics of base oils could represent a very valid tool for lubricant manufacturer choice, especially for the formulation of lubricants with very high performance.

ACKNOWLEDGMENTS

The author is particularly grateful to ENI Group S.p.A and Agip Petroli S.p.A for financial support of his work on lubricants, to Dr Carlo Corno for helpful discussions and suggestions and to Mr Walter Stringo for his technical contribution.

Lubricant base oils, or base stocks, are hydrocarbon lubricant components which are combined with performance additives to make finished industrial and automotive lubricants. A lubricant is a substance that reduces friction and wear between surfaces. Base oils typically comprise 80–99% of the finished lubricant. They are refined from selected crude oils, re-refined from used oil, synthesized from specific organic compounds, or extracted from renewable resources, such as seed oils. Base oils formulated into finished lubricants help to reduce friction and wear between moving surfaces, remove heat, seal, cushion against shock loads, and remove abrasives and contaminants from the lubricated area. Base oil analysis and characterization is important for understanding how the physical and chemical properties of these materials relate to performance in finished lubricants. It is also essential for maintaining quality control (QC) over the manufacturing process, for quality assurance (QA) of the finished product, and for setting specifications between buyer and seller.

1 INTRODUCTION

Base oils are refined from crude oil, re-refined from used oil, or manufactured to give products with specific chemical and physical properties. Mineral oils are base oils produced from the atmospheric residuum of crude oil. The residua are processed to remove aromatics and nitrogen-, sulfur-, and oxygen-containing compounds which degrade the performance of the finished base oil. Mineral base oils are classified by the molecular type that predominates (paraffinic, naphthenic, or aromatic) and their physical and chemical properties.

Paraffinic base oils tend to have high pour points and must be dewaxed to produce a base oil with acceptable flow properties at low temperatures. Naphthenic base oils have a naturally low wax content and generally have better solvency properties than paraffinic stocks. However, they tend to oxidize more readily than paraffinic oils. Aromatic stocks are valued for their solvency properties rather than their lubricating quality, and are used as process oils in the rubber and printing ink industries. Typical properties of paraffinic, naphthenic, and aromatic oils are shown in Table 1.[1]

High-quality re-refined base oils are processed to be indistinguishable from virgin mineral oils derived from crude oil. They are derived from contaminated used oils from a variety of sources. Analyses of re-refined base oils may include tests for contaminants in used oil that are not found in virgin base oils. (Refer to the appropriate American Society for Testing and Materials (ASTM) standard.[2] Unless stated otherwise, all references to ASTM methods are from the *Annual Book of ASTM Standards*, Vol. 05.)

The most commonly used synthetic base oils fall into one of five classes: olefin oligomers, especially polyalphaolefins (PAOs),[3,4] esters (dibasic and polyol), alkylated aromatics, polyalkylene glycols, and metalloorganic oligomers (phosphate or silicate esters, siloxanes).[5] Chlorine and/or fluorine-substituted hydrocarbons or polyethers are specialty lubricants used where extreme operating conditions are encountered.

Several general references on base oil technology, applications, and characterization have been published and are widely available. Neale has edited a tribology handbook with an excellent review of base oil types and their properties.[6]

Klaus and Tewksbury provide a comprehensive review of base oil and finished lubricant properties.[7] The ASTM has published a monograph on testing petroleum products following ASTM methods[8] and an educational guide on base oil characterization tests which covers lubricant performance and safe handling, composition, performance, and consistency.[2] The

journal *Analytical Chemistry* issues a comprehensive, biennial review on the analysis of petroleum and coal which includes lubricants and base oils.[9] For a broader perspective on lubricants, applications, lubricant characterization, and performance, Caines and Haycock[10] have written a reference book on automotive lubricants, and the Association of Iron and Steel Engineers (AISE)[11] has published a manual on industrial lubricants.

2 BASE OIL REFINING PROCESSES

Base oils are traditionally made by solvent refining to physically extract undesirable aromatics and heteroatomic compounds from the feed, solvent-assisted wax crystallization (paraffinic crudes), and clay treatment to decolorize and stabilize the finished product. In more modern processes, some refiners have replaced solvent refining with hydrocracking or severe hydrotreating, solvent dewaxing with catalytic dewaxing or wax isomerization,[12] and clay treating with hydrofinishing. Mineral base oils with properties approaching those of PAOs have been manufactured by isomerizing wax derived from slack wax or Fischer–Tropsch synthesis.[13,14] Base oils produced from vacuum distillates are called neutral oils; bright stocks are base oils refined from vacuum.

3 BASE OIL COMPOSITION

Base oil characterization is important for understanding the relationship between composition and performance of finished products in end-use applications. Rig or engine tests, developed to predict field performance, are often expensive or take a long time to complete. Consequently, a need exists for relatively simple, low-cost tests to predict the performance of a finished lubricant in the customer's equipment.

3.1 Hydrocarbon Type Analysis

Base oils derived from petroleum are complex mixtures of thousands of individual compounds. To better understand how base oil molecular structure, composition, and properties relate to product performance, investigators have examined individual model compounds and characterized the bulk molecular hydrocarbon types in base oils. Over a 26-year period, American Petroleum Institute (API) sponsored a program to measure the properties of 321 high-molecular-weight hydrocarbons.[15] Briant has provided a thorough analysis of these and other data on model compounds.[16]

ASTM has published several test methods to obtain information on the composition of base oils. ASTM D 2140[17] and D 3238 give calculated values for the carbon number distribution among aromatic, naphthenic, and paraffinic compounds based on viscosity (ASTM D 445),

density/specific gravity (ASTM D 1481), and refractive index (ASTM D 1218). ASTM D 3238, also known as the refractive index–density–molecular weight (n–d–M) method, gives similar, though not identical, results to ASTM D 2140.

More detailed base oil compositional information can be obtained by first separating base oil into aromatic and non-aromatic fractions on a chromatographic column and analyzing each fraction separately by mass spectrometry (MS). ASTM D 2549 describes a chromatographic procedure for separating hydrocarbon mixtures boiling between 232 °C and 538 °C on a packed column. The non-aromatics fraction is subjected to analysis by high ionizing voltage MS (ASTM D 2786) to give composition by seven saturated hydrocarbon types and one aromatic type. The aromatics fraction is analyzed by high ionizing voltage, low-resolution MS.

ASTM D 2007 (Clay-gel Analysis) and a technique developed by Hirsch et al.[18] are column chromatographic procedures used to separate high-boiling petroleum fractions into saturated, aromatic, and polar compounds. Barman[19] showed that ASTM D 2007 is subject to cross-contamination of these hydrocarbon classes. Thin-layer chromatography (TLC) with flame ionization detection (FID) is more rapid and accurate. Mohindroo and Preston[20] used supercritical-fluid chromatography (SFC) with flame ionization and ultraviolet (UV) detectors to separate base oils into saturates, polars, monoaromatics, and polynuclear aromatics. Hsu et al.[21] developed a rapid, preparative scale, high-pressure liquid chromatography (LC) procedure to separate base oils into compound groups using two columns and solvents of different polarity.

Thermal diffusion allows separation of hydrocarbons by molecular size under the influence of a thermal gradient. Cyclic and linear molecules diffuse by convection towards opposite ends of the apparatus. The process is time-consuming, but it provides detailed information not available by bulk chromatographic separation.[22]

Chromatography separates compounds into distinct molecular types but provides no quantitative information on the number of aromatic and paraffinic carbon or hydrogen atoms in each fraction. Nuclear magnetic resonance (NMR) and infrared (IR) analyses provide this information directly. ASTM D 5292 describes an NMR method to measure the mole or mass percent of aromatic carbon or aromatic hydrogen atoms in a sample. A. van de Ven et al.,[23] developed an improved correlation between ^{13}C NMR and IR analysis using the aromatic bands at 1610 cm^{-1} and 815 cm^{-1} to quantify the mole percent aromatic carbon in a base oil.

UV absorption (ASTM D 2008) is used to detect total aromatics in a sample, especially in severely hydroprocessed base oils, waxes, and white oils where the aromatics content is low. In ASTM D 2269, aromatics are concentrated before UV analysis by dimethylsulfoxide (DMSO) extraction. Similar procedures have been developed to assess the potential carcinogenicity of base oils and aromatic extract distillates.[24,25]

3.2 Elemental Analysis

Compounds containing nitrogen, oxygen, and sulfur in base oils can have profound effects on the properties and performance of finished lubricants. Elemental analyses are conducted to detect base oil contamination or impurities which survive the process of re-refining used oils. ASTM D 6074 provides a comprehensive list of tests to characterize hydrocarbon base oils (mineral oils) including those for elemental analysis. Sieber and Salmon[26] give an excellent summary of the instrumentation and methodology for spectrometric methods of lube oil analysis.

4 PHYSICAL AND CHEMICAL PROPERTIES

Physical and chemical properties of base oils can be related, ultimately, to their bulk or molecular properties. Physical property tests are used for manufacturing process control, QC, QA, consistency of finished products, and to set specifications between buyer and seller.

4.1 Viscosity

Viscosity is the critical factor in establishing hydrodynamic or full-film lubrication which reduces friction and wear between moving parts. Viscosity is defined as the ratio of shear stress to shear rate and measures resistance to flow. Newtonian fluids, including base oils above the cloud point, obey this equation. Klaus and Tewksbury,[7] Briant et al.,[27] and Alexander[28] provide detailed descriptions of rheology theory and applications to lubricants.

Dynamic, or absolute, viscosities are most often measured in coaxial-cylinder viscometers.[29] Kinematic viscosities are determined by ASTM D 445 which measures the time for a liquid to move through a narrow capillary segment. Absolute viscosity in millipascal sec. or centipoise (cP) equals kinematic viscosity in $mm^2\,s^{-1}$ or centistokes (cSt) times density ($g\,cm^{-3}$). Viscosities are typically reported at two temperatures, 40 °C and 100 °C, and a property defined as the viscosity index (VI) is calculated from the values (ASTM D 2270). High VI oils exhibit a relatively small change in viscosity with temperature. Aliphatic paraffins predominate in high VI oils (Table 1). ASTM D 341 describes a procedure and conditions to calculate the viscosity at one temperature from viscosities measured at two other temperatures.

Table 2 Low temperature – low shear rate tests

Test	ASTM D	Cooling Rate, °C	Shear Rate, s^{-1}
ASTM cloud point	2500	0.6/min	0
ASTM pour point	97/5949/5950 5985	0.6/min	0.1–0.2
Stable pour point	([a])	0 to −40/7 days	0.1–0.2
Mini rotary viscometer	3829	2/h	<100
Mini rotary viscometer	4684	0.33–2.5	<100
Brookfield viscosity	2983	Shock	0.1–12
Scanning Brookfield	5133	1/h	1.7

[a] Federal Stable Pour Test (FED-STD-791, Method 203), Naval Publications and Forms Center, Philadelphia, PA 19120, USA; SAE J-300, Appendix B, Society of Automotive Engineers, Warrendale, PA 15096, USA.

Viscosity also changes with respect to pressure, but the effect is much smaller than the temperature effect. Viscosity–pressure relationships are important in highly loaded contacts in gears or rolling element bearings, where the pressures under elastohydrodynamic lubrication can exceed 345 MPa (50 000 psi). Viscosity as a function of pressure can be measured in falling-weight viscometers, capillary viscometers, vibrating-crystal viscometers, and optical viscometers.[30] The effect of pressure on viscosity decreases in the order naphthenics > paraffinics > esters.

Apparent viscosities of non-Newtonian fluids vary with shear rate and shear stress. These include base oils below the cloud point and fully formulated lubricants containing high-molecular-weight components (VI improvers). For engine oils, high-temperature–high-shear viscosity at 150 °C and $10^6\ s^{-1}$ shear rate represents lubrication conditions in high-speed bearings. Methods to measure viscosity under these conditions include the Tapered-bearing Simulator (ASTM D 4683), Tapered-plug Viscometer (ASTM D 4741), and Multicell Capillary Viscometer (ASTM D 5481).

The Cold-cranking Simulator (CCS) (ASTM D 5293) measures low-temperature base oil viscosities at 10^4–$10^5\ s^{-1}$ shear rates. Wax-related viscosity effects are minimized, and measured viscosities are similar to extrapolated viscosities from data obtained above the cloud point. CCS viscosities of fully formulated engine oils correlate with low-temperature engine startup.

4.2 Wax-related Properties

As paraffinic base oils are cooled, wax crystals grow and form interlocking networks throughout the fluid which eventually stop oil flow at low shear rates. The shear stress required to break down the wax structure and resume lubricant flow is called the yield stress. Several tests have been developed to measure low-temperature, engine oil viscosities at low shear and low shear stress after long cooling cycles. Test conditions mimic, but don't necessarily duplicate, conditions that can cause low-temperature engine oil pumpability failures in the field. Except for the cloud- and pour-point tests, methods listed in Table 2 were developed specifically for fully formulated engine oils.

4.3 Volatility

Base oil volatility is an important factor in crankcase oil consumption, especially at high engine temperatures. Volatility decreases as VI increases for a given viscosity base oil and distillation cut width.

Volatility is measured by an evaporative-loss test (Noack) or gas chromatography (GC) (simulated distillation). In the Noack test, the weight of oil evaporated at 250 °C in one hour in flowing air is measured. Variations of the Noack test exist as Coordinating European Council (CEC) L-40-T-87,[31] Japanese Petroleum Institute (JPI)-5S-41-93, Method B,[32] and ASTM D 5800. An alternative apparatus has been proposed which eliminates use of toxic Woods metal as the heat-transfer medium and allows nearly quantitative collection of the volatiles for further analysis.[33] GC simulates distillation, and is more rapid and precise than Noack methods. ASTM D 2887 measures boiling-point distribution for hydrocarbons boiling between 55 °C and 538 °C. ASTM D 5480 uses an internal standard and was developed specifically to measure volatility of engine oils. Noack volatility is typically 5–15% higher than ASTM D 2887. Choi and Deane,[34] showed that two base oils with the same Noack volatility could have different volatilities by ASTM D 2887, and vice versa. Engine oil volatility at high engine operating temperatures appears to correlate better with Noack volatility.

4.4 Other Properties

ASTM D 6074 summarizes the tests used most often to characterize base oils and finished oils. ASTM D 6158 lists the specific tests and specifications for mineral hydraulic oils, including noncompounded base oils. Klaus and Tewksbury[7] and Godfrey and Herguth[35] describe base oil properties from a more fundamental viewpoint and

provide typical properties for different chemical classes of lubricants. The Annual Book of ASTM Standards, Volume 05, describes over 150 test procedures useful for testing or characterizing base oils.

Base oil characterization involves testing and assessment of appearance, viscometrics, safety, interfacial properties, solvency, oxidation and thermal stability, seal compatibility, and volatility. Appearance is determined by color (ASTM D 1500), cleanliness (International Organization for Standardization (ISO) 4406), and clarity (ASTM D 4860). Water above 80–100 ppm, for example, will impart a haze to base oils at room temperature. Color stability can be estimated by light irradiation, either by UV source or sunlight. Mills and Melchior[36] showed that color instability is due to nitrogen and sulfur heterocyclic compounds in base oils. Safety aspects include flash point (ASTM D 92/93) and toxicity (sections 6 and 7). Flash point is a rough measure of volatility and is used to detect low-boiling contaminants in base oils.

Interfacial properties between water and lube oil determine the demulsibility or the speed and efficiency of separating a mixture of the two (ASTM D 2711). Gas release (ASTM D 3827) and foaming tendency (ASTM D 892/6082) relate to the interfacial properties between base oils and gases. Copper corrosion (ASTM D 130) indicates presence of reactive sulfur compounds in base oils.

Solvency for additives and seal compatibility are governed by the chemical composition of base oils. Highly paraffinic base oils (hydrocracked mineral base oils and PAO) tend to shrink rubber seal materials and have lower solubility for additives than mineral oils containing aromatics and naphthenes, or synthetic base oils containing esters. Aniline point (ASTM D 611) is a useful guide to mineral base oil aromaticity and solvency properties. The effect of base oils and formulated lubricants on seal materials is determined by methods ASTM D 412/471/2240[37] and 5662.

5 EFFECT OF BASE OIL COMPOSITION ON LUBRICANT PERFORMANCE

Bench and rig test studies of base oils and formulated lubricants are used as guides to performance of fully formulated oils in field applications. The goal is to reduce the testing cost and maintain a high confidence level of performance when one base oil is substituted for another in a fully formulated lubricant. Hsu[38] conducted a thorough review of bench tests used to correlate performance of crankcase oils.

5.1 Oxidation Tests

Base oil oxidation tests can be classified as oxygen diffusion-limited (bulk), or reaction rate-controlled (thin film). Tests are run with or without catalyst activator. Catalysts simulate surfaces or contaminants that might accelerate oxidation. Oxidation-test results on uninhibited oils can be misleading. Highly paraffinic oils with low sulfur and nitrogen content oxidize more readily than base oils containing sulfur and aromatics, but are more stable with added oxidation inhibitor.[39]

Bulk oil oxidation tests include the oxidation test for turbine oils (The Institute of Petroleum (IP) 114), turbine oil stability test (ASTM D 943/4310/IP 157), rotary bomb oxidation test (ASTM D 2272), corrosiveness and oxidation stability of highly refined oils (ASTM D 4636/FTM 791-5308), and the universal oxidation/thermal stability test (ASTM D 4871/5846). Except for the rotary bomb test, which is conducted in a pressurized vessel, oxidation stability is evaluated at atmospheric pressure in flowing air.

Hsu and Cummings[40] developed a thin-film, thermogravimetric analysis (TGA) test to determine oxidation, volatility and extent of polymerization of base oils. Yoshida, Stipanovic et al.[41] used high-pressure differential scanning calorimetry (DSC) to measure base oil oxidative stability and correlated results with ASTM D 943. Klaus et al.[42] developed the Penn State Micro-oxidation Test to evaluate oxidative and thermal stability of base oils, and correlate lubricant degradation processes with those observed in automotive and diesel engine tests. Lubricant is oxidized in a thin film. Residues are analyzed by gel permeation chromatography (GPC). Selby[43] recommended the thin-film oxygen uptake test (TFOUT), ASTM D 4742, to determine base oil consistency and quality.

5.2 Correlation of Base oil Composition and Lubricant Performance

As a general rule, base oil oxidation stability increases with increasing saturates content, and sulfur compounds are beneficial at high temperatures in uninhibited oils or when inhibitors have been depleted.[44] Murray et al.[45] concluded that the relationship between VI and oxidation performance of solvent-refined base oils held only for base oils from the same crude source and refining process. Robson[46] found that oxidation of lubricants formulated with hydrocracked base oils correlated inversely with aromatics content. Sulfur did not correlate at the low levels found in the hydroprocessed lubes. Stipanovic et al.[41] used base oil compositional analysis, physical property measurements, and engine test results to develop predictive models based on partial least squares (PLS) and neural networks analyses. Multi-ring naphthene and polyaromatic compounds, thioaromatics, basic nitrogen compounds, and ''resins'' increase oxidation, thermal decomposition, and deposit formation. Supp et al.[47] also found that base oil sulfur increased sludge formation in

the Sequence VE test, but noted that aromatics, especially highly polar base oil components, were beneficial, possibly because they solubilize sludge precursors.

6 TOXICOLOGY

Crude oil atmospheric residua contain polynuclear aromatic, nitrogen-, and sulfur-heterocyclic compounds, some of which may be carcinogenic. While base oil refining removes some or all of these materials, the manufacturer is still responsible for assuring that the final products are non-carcinogenic. Blackburn[48] has reviewed the subject, and background information on test procedures and legal definitions of carcinogenicity are discussed in ASTM D 6074.

Mouse-skin bioassay is the most recognized, direct method for predicting the carcinogenicity of base oils.[49] The time of tumor development and the percentage of animals developing tumors relative to the controls are used to assess carcinogenicity. A bioassay test and DMSO extraction tests have been developed to predict the results of mouse-painting tests to reduce the time and cost to assess carcinogenicity. The Mutagenicity Index (Modified Ames Test), ASTM E1687,[50,51] is a short-term, microbiological, salmonella mutagenesis assay developed to detect mutagens in base oils. The correlation of mutagenicity and carcinogenicity with PNA content is defined for oils with viscosities >18 cSt at 40 °C, distilling between 250–550 °C. A new test to predict base oil carcinogenicity, DNA adduct formation, is now available.[52]

Method IP 346 specifies DMSO extraction of polycyclic aromatics and condensed-ring polar compounds in virgin base oil and measurement of the polycyclic aromatics in the extract.[53] The scope and limitations are described in the CONCAWE review[24] and the European Union Dangerous Substances Directive.[54] Haas et al.[25] developed another DMSO extraction procedure which is similar to ASTM D 2269. The index they developed includes both PNA content and viscosity to predict results from mouse-painting studies.

7 ENVIRONMENTAL IMPACT OF BASE OILS

Environmental impact is assessed by estimating the ecotoxicity and biodegradation of lubricants. Biodegradation is the oxidative decomposition of carbon, hydrogen, and oxygen compounds by microorganisms. Ecotoxicity is the tendency of a material to negatively impact nonhuman organisms.

The general order of biodegradation of base oils is vegetable oils > synthetic esters > mineral oils ~ alkylbenzenes > polyalkyleneglycols > PAOs.[5] The relative order depends on the test conditions and method of reporting. Within a family group, lower-molecular-weight compounds degrade faster and more completely than higher-molecular-weight materials.[4]

Biodegradation processes follow two paths. ''Ultimate'' biodegradation leads to complete biochemical oxidation to carbon dioxide, water, and inorganic salts. ''Bioaccumulation'' or ''primary biodegradation'' is a process in which the original molecule is partially degraded and incorporated into a microorganism as biomass. ''Primary biodegradation'' is followed by monitoring the disappearance of the original substance, while ultimate biodegradation is measured by carbon dioxide production or oxygen consumption.

ASTM D 6046 is a standard classification of hydraulic fluids for their environmental impact. While the document pertains specifically to the biodegradability and acute aquatic toxicity of hydraulic fluids, the methodology and test procedures identified also apply to base oils. ASTM published a companion document, ASTM D 6081, which covers standard practices for aquatic toxicity testing of lubricants and their components. Voltz et al.[55] and Kiovsky et al.[56] reviewed lubricant biodegradation test methods, and provided comparative test data on base oils and fully formulated oils.

The complex chemistry and chemical engineering of fossil fuel materials including petroleums, coal-derived liquids, tar sands, shale oils, refinery streams and refined products can often be adequately simplified by expressing the composition of these materials in terms of group types. Group (chemical) types are series of homologous compounds that exhibit similar chemical properties and a regular gradation of physical properties. A homologous series of compounds, the members of which are termed homologs, contains compounds in which successive members exhibit the same difference in chemical formula with the homologous unit of present interest being CH_2. Mass spectrometry (MS) is an ideal, extensively used technique in analyzing for chemical types in terms either of the total amounts of the various homologous series of compounds present in a sample or of the individual members (homologs) of the various series of homologous compounds present in a sample. The focus of this article is the fundamentals of homolog-type analysis because analyses expressed in terms of the amounts of individual homologs rather then in terms of the total amounts of group types benefits the understanding/prediction of the effect of experimental conditions on feedstock production/transportation, product distributions in feedstock refining, end-product quality and environmental impacts. A homolog-type analysis also permits the determination/prediction of chemical/physical properties of a sample that can be expressed as a function of composition; examples being reaction rates, distillation curves and elemental analyses. The discussion of techniques for obtaining the ''molecular ion mass spectra'' required to produce homolog-type analyses focuses on the use of all glass heated inlet systems (AGHIS) and direct probes for sample introduction, low-voltage electrons for ion formation, and double focusing magnetic sector (DF) and Fourier transform ion cyclotron

resonance (FTICR) mass analyzers to resolve isobaric ions.

1 INTRODUCTION

The complex chemistry and chemical engineering of fossil fuel feedstocks including petroleums, coal-derived liquids and tar sands and shale oils, refinery streams and refined products can often be adequately simplified by expressing the composition of these materials in terms of series of compounds that exhibit similar chemical properties and a regular gradation of physical properties. Such series of compounds have historically been termed group types. However, the phrases ''group-type'' and ''chemical-type'' are taken to be synonyms throughout this article. The concept of homology is implicit in this approach to formulating such analyses. A homologous series of compounds, the members of which are termed homologs, contains compounds in which successive members exhibit the same difference in chemical formula.

Mass spectrometric methods for performing chemical-type analyses can be classified according to whether the analytical results are expressed in terms of the total amounts of the various homologous series of compounds present in a sample or the individual members (homologs) of the various series of homologous compounds present in a sample. The extensive literature devoted to the development and applications of mass spectrometric techniques for performing such analyses over the past 50 years testifies to their extensive use in the fossil fuel industry.[1–98] The intent of the literature cited here[1–98] is to provide those who are new to the field of homolog-type analysis with an introduction to this body of literature and to provide both a background and framework for this article which focuses on the fundamentals of homolog-type analysis. The author apologizes to any of his colleagues whose work was not cited.

This article focuses on the fundamentals of homolog-type analysis for a number of reasons. High-resolution mass spectrometric (HRMS) methods are generic in terms of analyzing for chemical types whereas low-resolution methods necessarily assume that the group types comprising the sample are known. Analyses expressed in terms of the amounts of individual homologs rather than in terms of the total numbers of group types clearly benefits the understanding/prediction of the effect of changes in experimental conditions on chemical and physical processes affecting issues such as corrosion, product distributions, end-product quality and environmental impact. Finally, a homolog-type analysis permits prediction of any chemical or physical property of a sample that can be expressed as function of composition. Examples include the calculation of reaction rates, mass balances, average molecular weights for each chemical type and for the sample, the distillation characteristics for each group type and for the sample and elemental analyses for the predicted distillate cuts and the total sample. The discussion of techniques for obtaining ''molecular ion mass spectra'' focuses on the use of AGHIS and direct probes for sample introduction, low-voltage electrons for ion formation, and DF magnetic sector and FTICR mass analyzers to resolve isobaric ions. Topics considered in processing these spectra include the assignment of formulas to ion masses obtained from the conversion of time centroids and frequencies in mass spectra acquired using DF and FTICR instruments, respectively, the generation of quantitative distributions from molecular-ion abundances and the calculation of chemical/physical properties from these distributions. In writing this article the author hopes to accomplish in part the goals of providing the individual who is new to the field with an introduction to the fundamentals of HRMS homolog analysis and with an indication of issues in these methods that need to be addressed and resolved.

2 GROUP (CHEMICAL) TYPES

2.1 Definition and Significance in Terms of the Concept of Homology

As noted above, compounds that differ in composition by CH_2, undergo similar chemical reactions and exhibit a regular gradation of physical properties under specific experimental conditions constitute a group or compound type. A chemical (group)-type is a homologous series of neutral or ionic substances. However, as discussed in section 2.3 a homologous series may contain more then one group type. Isomers differ in structure but not in formula and, hence, are subsets in a set of homologous substances. For example, benzene (C_6H_6), and benzene substituted with alkyl groups containing 1, 2, 3, 4, . . ., carbons differ in composition by CH_2 and, hence, correspond to a homologous series of compounds. The ionization of these compounds in a mass spectrometer produces a homologous series of molecular ions. Furthermore, isomers are subsets of homologs of benzene containing two or more alkyl carbons. For example, the third homolog in the series (C_8H_8) may reflect the presence of one or more of the four possible isomers, ethylbenzene and *o*-, *m*-, and *p*-xylenes. It should be noted that neutral and, hence, ionic homologs consist of compounds and ions containing the various isotopes of their constituent elements.

2.2 Mass Spectrometric Nomenclature: the Specific *Z* Series Concept

2.2.1 Naming Homologous Series

A homolog-type analysis is synonymous with the identification of the homologous compounds which constitute a sample. Unfortunately, the existence of isomers can complicate to varying degrees the nomenclature for these series. For example, benzene and benzene substituted with one or more alkyl groups may unambiguously be referred to as the benzene series with the number of alkyl carbons possessed by each homolog specified numerically. Thus, the name C-2 alkylbenzenes encompasses ethylbenzene and the isomeric dimethylbenzenes. However in many instances the existence of isomers makes this approach to nomenclature quite cumbersome. As an example, consider a homologous series of hydrocarbons beginning with naphthalene ($C_{10}H_8$). The phrase ''naphthalene series'' or simply ''naphthalenes'' would be acceptable nomenclature provided that only naphthalene and its alkylated homologs are present. However, hydroaromatic hydrocarbons such as **(1)** and **(2)**, indenes substituted with one alkenyl group such as **(3)** and naphthenoindenes such as **(4)** and the alkylated homologs of these hydrocarbons are isomers of alkylated naphthalenes containing the same number of carbons. If the series either contains or is believed to contain hydrocarbons such as **(1)** and **(2)** and their alkylated homologs in addition to naphthalenes then the series could be and often is referred to as the naphthalene/trinaphthenobenzene series. The possible presence of hydrocarbons such as **(3)** and **(4)**, isomers of these compounds and their alkylated homologs would require that the series be called the naphthalene/trinaphthenobenzene/alkenylindene/naphthenoindene series. Such difficulties in nomenclature are circumvented by using the *Z*-series concept to classify molecular ions and, hence, their precursor compounds according to the homologous series to which they belong.

2.2.2 Specific Z *Value*

The vast majority of organic compounds in petroleums, synthetic crudes, refinery streams and materials derived from their processing are derived from the combination of two or more of the elements carbon, hydrogen, nitrogen, oxygen and sulfur in various proportions by weight. Petroleums and syncrudes also contain varying amounts of organic compounds substituted with metallic elements such as nickel, vanadium and iron. The general formula of organic and organometallic compounds of present interest is $C_nH_xN_aO_bS_cNi_dV_eFe_f$. Homologs differ in composition by $1, 2, 3, 4, \ldots n$, CH_2 groups. Therefore, we associate $2n$ of the x hydrogens in the general formula with the n carbons leaving $x - 2n$ hydrogens. Thus, the general formula becomes $(CH_2)_nH_{x-2n}N_aO_bS_cNi_dV_eFe_f$. Homologs have the same value of the quantity $x - 2n$. This difference is defined as the specific Z value as shown in Equation (1)

$$Z = (x - 2n)(N_aO_bS_cNi_dV_eFe_f) \tag{1}$$

As seen in Equation (1), a homologous series is designated by the numerical value of Z followed by the symbols for and the numbers of the heteroelements that are present. The symbol H is used for designating hydrocarbons because all elemental coefficients other then those for carbon and hydrogen are zero. Thus, the general formula for compounds and ions of present interest may be written as $(CH_2)_nH_ZN_aO_bS_cNi_dV_eFe_f$.

Compounds and ions of present interest may be viewed as being derived from combinations of basic structural groups. Table 1 lists specific Z values for a number of these structural groups. Thus, the specific Z value for any species considered as being derived from these structural groups species is given by

$$Z = \sum_i \alpha_i Z(X_i) \tag{2}$$

Table 1 Specific Z values for structural groups

Group (X_i)	$Z(X_i)$
C	−2
CH	−1
$(CH_2)_n$	0
CH_3	1
H	1
X=N, O, S	0
XH=NH, OH, SH	1
C=O	−2
C−C/C=C/C≡C	−4
CH=CH	−2
CH=N	−1
C_6H_5	−7

Figure 1 Examples illustrating the specific Z series concept, prediction of Z values for species from Z values of functional groups and relation between Z values and rings plus double/triple bonds.

where α_i is the number of the ith structural group in the structure. From Table 1 and Equation (2) it follows that the number of rings plus double/triple bonds present in a species is

$$\mathcal{R} = \tfrac{1}{2}[2n - x + a + 2] \tag{3}$$

Solving Equation (3) for the quantity $x - 2n$ and substituting the result into Equation (1) results in the Equation (4) which expresses the specific Z value as a function of the number of rings plus double/triple bonds

$$Z(\mathrm{N}_a\mathrm{O}_b\mathrm{S}_c) = a + 2(1 - \mathcal{R}) \tag{4}$$

Figure 1 contains a representative number of examples that illustrate the application of the specific Z series concept, the use of the Z values for functional groups in Table 1 and the relation between the specific Z value and the number of rings plus double/triple bonds.

In the opinion of the author, the practice of referring to the specific Z value as the hydrogen deficiency should be discontinued for several reasons. For example, consider naphthalene ($C_{10}H_8$) which from Equation (1) has a specific Z value of -12(H). As applied to this compound, a logical question that never seems to be answered is what is the chemical significance of the statement

that naphthalene has a hydrogen deficiency of −12? A definition of hydrogen deficiency that has been used is the difference in the number of hydrogens between a compound and the alkane with the same number of carbons. Although this definition gives correct Z values for some species it is not generally valid because it predicts a specific Z value of −14(H) for naphthalene, that is, the difference in hydrogen numbers between $C_{10}H_8$ and $C_{10}H_{22}$ is −14. Addition of 12 hydrogens to naphthalene would presumably result in cyclodecane or a set of isomeric decenes. Another definition that can be found in the literature is the difference in hydrogen numbers between a species and a cycloalkane or an alkene. Clearly, this is a general definition with the caveat that the reference and subject species have the same carbon number. For example, consider pyrrole which has the formula C_4H_5N and hence, $Z = -3$(N). Thus, to get the correct Z value, the formula for pyrrole must be compared to an alkene or cycloalkane having four and not five carbons as the latter would yield $Z = -5$(N) for pyrrole. However this definition with or without the added caveat produces paradoxical results for alkanes. First, there is no alkene or cycloalkane to compare to methane. Second, the difference in hydrogen numbers between all alkanes having carbon numbers greater then 1 and the corresponding alkenes is +2. Thus, alkanes have a hydrogen deficiency of +2. That is, alkanes have an excess not a deficiency of hydrogens.

2.3 Deduction/Determination of Group Types from High-resolution Mass Spectrometric Homolog Analyses

Two concepts underlie mass spectrometric methods for homolog analysis. First, removal of an electron from a homologous series of compounds produces the corresponding series of homologous molecular ions. Thus, use of an ionization technique that generates mass spectra either dominated or characterized by the presence of molecular ions and the accurate measurement of the mass-to charge ratios of these ions suffices to identify the homologs present in a sample. Second, the signal magnitudes of these ions allow the contribution of each of these homologs to the sample to be calculated given quantitative relationships between the isotopically most abundant molecular ion signal magnitudes and the structures of the neutral precursors to these ions. As discussed in subsequent sections, implementation of these concepts is not necessarily straightforward. However, we assume the successful implementation of them in order to consider briefly the equally important topic of determining the number of group types present in a homologous series of compounds. In general, homologs may consist of two or more isomers. The chemistry of isomers depends upon the experimental conditions. Given the compositional complexity of materials of present interest, the possibility that homologous series may contain more then one chemical (group) type should be considered by both the analysts and the chemists/chemical engineers in planning the analytical scheme and/or interpreting the results of a homolog-type analysis.

Figures 2, 3 and 4 contain carbon number distributions (CNDs) from four homolg-type analyses. The phrase ''carbon number distribution'' refers to the format conventionally used in reporting the results of homolog-type analyses. The numbers of the homologs identified as being present in a sample are normally calculated on

Figure 2 CNDs for the −6(H) (×) and −12(H) (○) Z series obtained from high-resolution FI mass spectra of the aromatic neutrals from separation of coal–liquid-derived oils.

Figure 3 CNDs for the −18(H) Z series in a gas oil and the monoaromatic, diaromatic and triaromatic fractions from its ring number separation. ○, total aromatics; △, ring fraction 1; ×, ring fraction 2; +, ring fraction 3.

a percentage or absolute weight, mole or volume basis. The results are usually reported as a two-dimensional array. The rows or columns are the specific Z series designations for the homologous series and the columns or rows correspond to the number of carbons present in each homolog. Since the numbers of the members of each homologous series identified as being present in the sample are reported as a function of the number of carbons present in each homolog, the tabulation is termed a CND. Figures 2, 3 and 4 contain weight percentages normalized to a value of 100 for the most abundant homolog in the more abundant series, if two or more series are present.

Figure 2 contains CNDs for the -6(H) and -12(H) series obtained from high resolution field ionization (FI) mass spectra of the aromatic neutrals from chromatographic separation of coal–liquid-derived oils.[61,99] The -6(H) aromatic series can only contain benzene, toluene and either *n*-alkylated benzenes or isomeric benzenes substituted with two or more alkyl groups or both. Thus, we conclude that the -6(H) CND in Figure 2 reflects the presence of a single group-type consisting of homologs of benzene which have 3–23 alkyl carbons.

Figure 4 CNDs for the -14(H) Z series in an anthracene oil and in a hydrotreated product. ○, in feed; △, in products; ×, feed group-type in products; +, nonfeed-type(s) in products.

The nature of a CND can often yield significant inferences concerning the presence or absence of more then one group type in a homologous series. For example, in Figure 2 the first member in the -12(H) series has the formula $C_{10}H_8$ and, hence, reflects the presence of naphthalene. This result, the shape of the distribution and the fact that the $C_{10}-C_{16}$ homologs dominate the distribution, leads to the conclusion that the -12(H) series is reasonably attributed to the presence of a single group type, that is, naphthalene and its alkylated homologs. However, definitely to exclude compound types such as **(1–4)** as significant contributors to the -12(H) series would require additional experiments such as performing HRMS analyses on fractions obtained from a ring number separation of the aromatic neutrals.

The bimodal CND for the -18(H) series in Figure 3 clearly indicates the presence of at least two group types. The first homolog in the series has the formula $C_{14}H_{10}$ and is attributed to the presence of anthracene **(5)** and/or phenanthrene **(6)**. Either one or both of these hydrocarbons containing 1–6 alkyl carbons undoubtedly contributes to the $C_{15}-C_{20}$ homologs. However, the shape of the distribution is evidence that at least one additional group type contributes to homologs which have carbon numbers greater than 20. As seen in Figure 3, the CNDs for the -18(H) series from the HRMS analyses of the fractions from the ring number separation of the total aromatic neutrals substantiates this conclusion. The results for the monoaromatic or first ring fraction reveal the presence of a group type consistent with the presence of hydrocarbons containing one aromatic and six naphthene rings such as **(7)** and their alkylated homologs. The results for the second ring fraction support the presence of a diaromatic chemical type reflecting the presence of hydrocarbons such as trinaphthenonaphthalenes and alkylated homologs of these hydrocarbons. The results for the third ring fraction confirm the presence of a three aromatic ring chemical-type containing 14–36 carbons.

CNDs for the -14(H) series in an anthracene oil and one of the products from its hydrotreating are reproduced in Figure 4.[60] The distribution for the feed is consistent with the presence of a single chemical type. This conclusion is supported by gas chromatography/mass spectrometry (GC/MS) analysis which revealed that acenaphthene **(8)** and biphenyl **(9)** accounted for 94% and

$C_{14}H_{10}$ **(5)**

$C_{14}H_{10}$ **(6)**

$C_{25}H_{32}$ **(7)**

6% of the first homolog, respectively.[60] The CND for the −14(H) series in the products shows that hydrotreating deceased the weight percentages of the C_{12} and C_{13} homologs and resulted in significant increases in the amounts of the C_{14}–C_{18} homologs. This and other results show the occurrence of both hydrogenation reactions introducing hydroaromatics such as **(10)** and **(11)** and hydrogenation/hydrogenolysis reactions introducing aromatics such as **(12)** and **(13)** into the −14(H) series. Estimates of the percentage contributions of **(8)** and **(9)** and homologs of these hydrocarbons and products formed from the hydrogenation of phenanthrenes **(10)** and **(11)** and hydrogenation/hydrogenolysis of phenanthrene **(12)** and pyrene **(13)** to the −14(H) series in the products are shown in Figure 4. These estimates were obtained by assuming that the C_{13}–C_{18} homologs in the feed undergo the same percentage decrease as does the C_{12} homolog.

High-resolution low-voltage electron ionization mass spectra (HRLVEIMS) of fossil fuel materials which have atmospheric equivalent boiling points (AEBP) up to about 1050 °F (566 °C) will in general contain series of molecular and fragment ions. The fragmentation processes undergone by molecular ions in a given homologous series and the yields of these ions relative to the molecular ions depends upon a number of factors which are considered in section 7. What is of present interest is the fact that the presence of these fragment ions must be taken into account in processing mass spectra in order to avoid erroneous conclusions regarding the group types present in a sample. The occurrence of this phenomena is illustrated in Figure 5, which contains a plot of the −6(H) homolog molecular ion relative abundances versus carbon number and could be interpreted as reflecting the presence of a −6(H) series in a >650 °F (343 °C) AEBP distillate that contains homologs with carbon numbers ranging from 7–40. However, such a conclusion would be erroneous for two reasons. First, the initial carbon number in the series would be expected

Figure 5 Plot of the relative signal magnitudes versus carbon number for the −6(H) *Z* series in the high-resolution low voltage mass spectrum of gas oil aromatic neutrals.

to be about 15, based upon the boiling range of the sample. Second, one fragmentation reaction of benzene molecular ions substituted with relatively long-chain alkyl groups phenomenologically involves hydrogen transfer from the alkyl group to the ring with loss of an alkene resulting in formation of parent ions.[100,101] Although this process is dominated by α-cleavage at 70 eV, it becomes relatively important at low voltage.[100,101] Thus, the ion abundances from carbon numbers 7 to about 14 are attributed to the occurrence of such rearrangement fragmentation reactions.

3 SAMPLE PREPARATION

It is generally necessary to subject crude oils, syncrudes and materials derived from their processing to physical and/or chemical separations prior to determining the compositions of these materials. An in-depth discussion of the numerous techniques available for performing these separations is clearly beyond the scope of this article. Rather the intent of this section is simply to provide the reader with an overview of a number of approaches to generating fractions that are suitable for analysis. The reader should be aware of the fact that the approach to separating a given material appears often to be determined either by the past history of the analytical chemistry of a given fossil fuel material or by the preferences of a given research group.

3.1 Distillation

Distillation is an important technique in the characterizations of crude oils. It has also been employed as the

first step in the analysis of other fossil fuel materials such as coal liquids and shale oils. Atmospheric pressure distillations resulting in distillate fractions boiling up to approximately 650 °F (343 °C) are conventionally performed using the American Society of Testing and Materials (ASTM) method D2892.[102] Middle distillates contain compounds boiling from about 400 to about 650 °F (205–343 °C). Gas oils or vacuum gas oils which have AEBPs ranging from approximately 650 °F (343 °C) to approximately 1050 °F (566 °C) are obtained by distilling the residue from a D2892 distillation at reduced pressure using ASTM method D1160.[103] Compounds having AEBPs up to about 1300–1400 °F (705–760 °C) can be recovered from a D1160 vacuum residue using the technique of molecular distillation.[104,105] It should be noted that these distillations produce fractions that do not have sharp cut points in terms of composition, with the degree of overlap tending to increase with increasing boiling point. Distillate cuts boiling up to 400 °F (205 °C) are amenable to analysis using techniques such as gas chromatography (GC) and combined GC/MS. Applications of HRMS group-type methods are usually limited to distillate cuts having initial AEBPs of at least 400 °F (205 °C).

3.2 Solvent Separations – Solvent Extractions

The development of coal-liquefaction technology has historically used the technique of solvent separation or solvent extraction to separate coal-derived liquids into fractions termed oils (maltenes), asphaltenes and preasphaltenes.[48,52,61,80,106] The technique has also been applied to other materials such as bitumens.[67] A high-performance liquid chromatography (HPLC) solvent fractionation technique based upon the solubility properties of solvents has been described.[105] Acidic and basic chemical extraction techniques have been used to recover basic and acidic compounds from syncrudes and petroleums.[50,72,79,80,82] It should be noted that the fractions obtained from solvent extractions are operationally defined in terms of the procedure used to generate them.

3.3 Liquid Chromatography

Liquid chromatography is used to separate crude oils, syncrudes and materials derived from their processing into compound classes. The nature of the fractions resulting from these separations are operationally defined in terms of the procedure used to generate them. One approach is to separate a sample into classes of compounds that exhibit for a given procedure either acidic, basic or neutral chemical properties. One method for generating acidic and basic compound classes uses ion-exchange chromatography to remove compounds that exhibit acidic and basic properties with respect to anion and cation resins, respectively.[107,108] Chromatography using $FeCl_3$ impregnated Attapulgus clay as the stationary phase has been used to remove nitrogenous compounds present in neutral fractions. A second technique for isolating acids and bases involves chromatography over acidic and basic alumina to recover compounds that exhibit basic and acidic properties, respectively.[77] A number of chromatographic procedures have been developed for separating neutral fractions into saturated and aromatic compound classes.[50,77,109,110] Solid–liquid chromatography using activated silica gel is required to separate saturates from aromatic neutrals. This separation can be performed using either HPLC or open column (low pressure) chromatography. Gradient elution chromatography through a dual-packed adsorption column containing silica gel and alumina has been used to separate neutral concentrates into saturate and operationally defined monoaromatic, diaromatic and polyaromatic-polar fractions, that is, compounds containing one, two, three or more aromatic rings and/or heteroatoms.[109] Preparative scale HPLC procedures employing stationary phases such as chemically bonded aminopropylsilica,[77] 2,4-dinitroanilinopropylsilica[110] and bonded charge-transfer agents[111] have been developed for fractionating aromatic neutral fractions into operationally defined compound classes such as monoaromatics, diaromatics, triaromatics and tetra and greater aromatics, that is, compounds containing one, two, three and four or more aromatic rings. It should be noted that the resolution achieved in these separations decreases with increasing boiling point.

4 SAMPLE INTRODUCTION

4.1 All Glass Heated (Batch) Inlet Systems

The introduction of fossil-fuel materials having AEBPs up to about 1050 °F (566°C) requires an inlet system capable of being heated and evacuated. The design should be compatible with the introduction of liquids and solids. Quantitative analysis of mass spectral data is necessarily simplified if the composition of the vapor entering the ion source is, at all times, functionally related to the original composition of the sample under analysis. Therefore, a reservoir of known volume is incorporated into the inlet system and a leak of known leak rate is inserted between the reservoir and the ion source. The sample is first expanded into the reservoir, hence, the term expansion volume, and then allowed to flow from the reservoir to the ion source via the leak. The glass line connecting the inlet system to the ion source housing is conventionally termed the leak line. The device which connects to the leak line at the source housing and conducts the vapor to the ion

source is termed the reentrance. All components of the inlet system including the leak line and the reentrance should be capable of achieving and maintaining the same temperature.

4.1.1 Inlet Designs

The first successful reservoir–inlet system meeting these criteria was developed by Lumpkin and Taylor.[112] Gallium was used to maintain the integrity of the vacuum within the inlet system during sample introduction. A capillary pipette was used to introduce volatile liquids via a gallium-covered fritted disk. Solids and relatively nonvolatile liquids were introduced using a removable, heatable holder containing gallium. All subsequently designed high-temperature reservoir inlet systems familiar to the author can be considered to be variants of the Lumpkin–Taylor inlet.[113–117] Recent versions of this inlet are described below.

The Brunfeldt AGHIS was a joint development between R.J. Brunfeldt of the Brunfeldt Co., Bartlesville, OK (presently located in Bixby, OK) and the author and other members of the Instrumental Section at the Bartlesville Energy Technology Center, US Department of Energy, Bartlesville, OK. The basic approach was to design an inlet system incorporating new technology while maintaining the salient concepts of the Lumpkin–Taylor inlet. The methods for sample introduction and for actuating the magnetically operated valves within the oven are shown in Figure 6. Figure 7 shows the construction of the oven and the components of the inlet system within the oven.

As shown in Figure 6, the valve lifters are activated by controls on the bottom of the oven. This design allows for immediate direct access to the interior of the oven by simply lifting off the top cover of the oven. The availability of high-temperature GC septums exhibiting negligible bleed permitted use of a heatable septum inlet for introduction of relatively nonviscous liquids as shown in Figure 6. Figure 6 also shows that a removable glass cup which is heated by an independent oven permits the introduction of solids and liquids having a wide range of volatilities because the initial temperature of the cup can be subambient. Optically flat glass surfaces on the top of the cup and at the end of the glass line exiting the oven assures the integrity of the vacuum.[114]

As seen in Figure 7, the oven incorporates a reservoir which has a volume of 900 mL. Figure 7 also shows the use of high-temperature ceramic insulation to maintain excellent temperature control within the oven. The sections of the septum inlet and the leak line passing through the oven walls are encased in aluminum blocks containing cartridge heaters in order to eliminate cold spots. As is evident in Figure 7, difficulties in performing any required maintenance is minimized by the capability of simply accessing the interior of the oven and by the location of components in the oven. The use of large diameter sample lines provides for rapid and complete residual sample removal. In order to achieve significantly reduced leak rates across the ball valves, each valve

Figure 6 Front of AGHIS oven showing septum and glass-cup inlets and controls for actuating magnetically operated valves.

Figure 7 Interior of oven in AGHIS.

is fabricated from glasses having dissimilar hardness. Placement of the valves provides for nonsynergistic variations of pressures within the inlet system.

The design of the reentrance needs to allow for expansion/contraction of the ion source as it is heated/cooled while maintaining good transport of the vaporized compounds into the ion source. With respect to the Kratos MS-50, this requirement was met by installing a Brunfeldt reentrance. This design incorporates threads on the end of the stainless steel housing of the reentrance which is matted via a vacuum flange and a gold gasket to a port in the ion source housing. A bellows and a threaded collar are used to vary the distance between the ion source and the reentrance tube. A thin glass helix inserted in the transfer line in the inlet oven allows for changes in the position of the leak line as the distance between the reentrance glass tube and the ion source is varied. The distance between the glass tube and the ion source is increased/decreased by decreasing/increasing the number of turns of the collar on the reentrance housing threads. For example, with the bellows in a relaxed position, the inlet oven, the leak line, the reentrance glass tube and the ion source are brought to a desired temperature. An aliquot of *p*-xylene is admitted to the inlet and the increase in the signal magnitude of the *m*/*z* 106 ion is monitored as the bellows is compressed to reduce the distance between the reentrance tube and the ion source. The onset of a decrease in the ion signal magnitude is used to establish the occurrence of contact between a port in the ion source and the reentrance tube. The collar is then turned in the opposite direction to relax the bellows first to remaximize the ion signal and then to decrease the ion signal slightly in order to achieve a slight distance between the ion source port and the reentrance glass tube. This procedure has been found to give good transfer of vapor into the ion source while maintaining excellent alignment of the source which is critical for achieving optimum performance of the mass spectrometer at high resolving powers (RPs). In addition, use of this reentrance was found significantly to reduce contamination of both the ion source housing and the glass electrical feedthroughs on the end flange of the ion source.

A turbomolecular pump backed by a mechanical pump is used to reduce the pressure in the system to less than 10^{-3} Torr [1 Torr = (101 325/760) N m^{-2}] as measured by a thermocouple gauge. The design of the power supplies that provide electrical power to the heaters incorporates temperature regulators connected to thermocouples. Thus, the temperatures in the various sections of the inlet including the cup inlet, oven, leak line and reentrance are controlled to within about ±2 °C. Temperatures as high as 325 °C are maintained routinely. The septum inlet has been operated at temperatures as high as 325 °C without noticeable thermal deterioration of the septum, although temperatures up to 300 °C are more commonly used. The time required to raise the temperature of the cup inlet to a given value can be significantly reduced by preheating the door heater shown in Figure 6, for example, the temperature in the cup-inlet oven rose from ambient to 300 °C in about 75 s after preheating the oven for about 4 min.

Gallegos and Pazzi reported the design of a miniature batch inlet system that they termed a dynamic batch inlet system (DBIS).[116] The system incorporated an expansion bulb with a volume of only 2 mL and was used in conjunction with a gas chromatograph. The bulb was placed in the GC oven with the inlet and outlet lines connected to the GC injector and the MS ion source using deactivated uncoated 0.25-mm fused-silica capillary tubing. Hydrogen was used as the carrier gas at a flow rate of about 1 mL min^{-1}. The temperatures of the injector, oven and transfer line were set to 300 °C. Injection volumes of samples such as a 350–550 °C AEBP distillate cut were 0.02–0.05 μL.

Roussis and Cameron evaluated the operational characteristics of a modified version of the Gallegos and Pazzi DBIS fabricated by the Brunfeldt Company.[117] Substitution of helium for hydrogen as the carrier gas and variations in the dimensions of the capillary lines resulted in residence times of at least 15 min. The ability to introduce samples without using a carrier gas was also reported. Excellent agreement was obtained between the results of low-resolution type analyses performed using the DBIS for sample introduction and the corresponding results obtained using a Brunfeldt AGHIS for sample introduction.

The following are several issues that must be addressed in any consideration of substituting a DBIS for an AGHIS in HRMS-type analysis. Although the ability to use small sample sizes would be a clear advantage of a DBIS over an AGHIS, which generally require samples sizes of 5–12 mg, the actual sample sizes required in HRMS applications and the implications for the required volume of the reservoir and the dimensions of the capillary lines connected to the DBIS would have to be determined. In addition, a further increase in the residence time would be required to permit acquisition of HRLVEIMS at a magnetic field scan rate of 1000 s/mass decade, for example, the time for acquiring 40 000–50 000 RP spectra at a magnetic field scan rate of 1000 s/decade is typically greater then 16 min. Also, design changes that would reduce the time-dependent variation in the ion signal magnitude observed by Roussis and Cameron and that would provide the capability for introducing viscous liquids and solids and for evacuating samples would be mandatory.

The problems encountered by the author and coworkers in attempting to use a GC oven-based inlet system developed by The Brunfeldt Company are relevant in regard to attempting to develop a DBIS for use in HRMS

group-type analyses. Vaporized samples were transferred from the reservoir to the ion source of the mass spectrometer using deactivated fused silica capillary tubing via the heated GC reentrance. Satisfactory flow rates and stable ion signal magnitudes were obtained by empirically adjusting the dimensions of the capillary tubing. The inlet system incorporated septum and cup-based inlets for introduction of liquids and solids. Unfortunately, the design placed these inlets inside of the GC oven. Thus, the introduction of samples required that the GC oven be cooled to room temperature. The excessive time required to raise the temperature to say 300 °C using only the GC oven heater was addressed by installing but not without problems an additional heater in the GC oven. A more serious problem that was never satisfactorily resolved was the effect of GC blower fan vibrations on 40 000 RP low-voltage electron ionization (LVEI) mass spectra.

4.1.2 *Effusive Flow and the Time Dependence of Ion Yields*

We now consider the effect of the time dependence of the sample composition in the reservoir on the relative ion abundances (RIAs). Since the rate of effusion of a gaseous species follows molecular flow and is inversely proportional to the square root of its mass,[118] the partial pressures of the components in the reservoir are time dependent. Thus, the composition of the gas flowing into the ion source is time dependent. The effect of neglecting to correct for this phenomenon on the accuracy of an analysis reflects the rate of effusion through the leak in relation to the masses of the gaseous species, the vacuum-seal integrity of the inlet system, mass spectral acquisition time and the reproducibility in the mass spectra. In order to assess the magnitude of the problem, let N_i. be the number of moles of the ith species having molecular weight MW_i in the inlet at time t (s) and at temperature T(K). Neglecting the steady state pressure in the ion source, the rate of decrease in N_i is[118]

$$\frac{-\mathrm{d}N_i}{\mathrm{d}t} = \frac{AN_i}{V}\left(\frac{RT}{2\pi MW_i}\right)^{1/2} \tag{5}$$

where A is the cross-sectional area (cm^2) of the leak, R is the gas constant (8.314×10^7 erg K^{-1} mol^{-1}) and V is the volume of the reservoir plus the glass line between the reservoir and the leak. Integrating Equation (5) between the limits $N(t_0)$, t_0 and $N(t_i)$, t_i, we obtain Equation (6)

$$\ln\frac{N(t_i)}{N(t_0)} = -k_{\mathrm{eff}}(t_i - t_0) \tag{6}$$

where

$$k_{\mathrm{eff}} = \frac{A}{V}\left(\frac{RT}{2\pi MW_i}\right)^{1/2} \tag{7}$$

The rate of effusion of air through a leak was found to be 0.21 cm s^{-1} at 298 K. Thus, Equation (7) yields an area of 1.80×10^{-5} cm^2 for the leak. The area of the leak was independently determined by monitoring the time dependence of the intensity of the molecular ion of acetone. The m/z 58 intensity decreased by a factor of two in 2398 s. Since the inlet temperature was 573 K and since V is 930 cm^3, Equations (6) and (7) yield an area of 2.35×10^{-5} cm^2. The good agreement between the two independent methods for determining the cross-sectional area of the leak demonstrates the vacuum-seal integrity of the inlet system.

The time dependence of the composition of a gaseous mixture in a reservoir inlet is considered assuming a mixture initially composed of equal moles of −6(H) series homologs. Assume that the magnetic field was scanned exponentially from m/z 650 to m/z 70 at 100 s/decade. Acquisition of mass spectra rather than elapsed time is of immediate relevance to the analyst. Therefore, Table 2 presents the effect of effusion of components across the leak on the composition of the mixture in the inlet as a function of the mass spectrum number rather than as a function of elapsed time following introduction of the sample into the ion source. In Table 2, the effusion constants in column 3 were calculated for the masses in column 2 using the values in footnote a. The values in column 4 are the arrival times for the seven molecular ions in a given mass spectrum calculated using the value specified in footnote c. Columns 6 through 15 list the moles of each of the seven components remaining in the inlet relative to the initial moles at the time of detection of each molecular ion in each of the ten mass spectra. As noted in footnote d, these values were calculated using the effusion constants and times in columns 3 and 4, respectively, assuming an elapsed time of 5 min between sample introduction to the ion source and initiation of the first scan and a total time of 6 s between scans.

Comparison of the mole ratios in columns 6 through 15 of Table 2 with the corresponding initial ratios in column 5 reveals that the moles of each component and, hence, their partial pressures, decrease with increasing time. The decrease in these quantities is seen to increase, as expected, with decreasing molecular weight. Therefore, the number of molecules of each component entering the ion source per unit of time diminishes as time increases with the diminution becoming larger as the molecular weight decreases. Consequently, consecutive scans of the mass spectrum of the mixture will exhibit progressively smaller values for both the molecular-ion signal magnitudes and the total ionization. In order to assess the impact of these observations on the accuracy of a quantitative analysis, it is useful to express the time dependence of the composition of the vapor remaining

[a] Values in columns 3 through 12 calculated from values in columns 6 through 15 in Table 2, respectively.

in the inlet in terms of the mole ratios normalized to the moles of one component because these values are directly proportional to the relative molecular-ion signal magnitudes observed in the mass spectra of a mixture. The values calculated from the relative mole ratios in Table 2 are tabulated in columns 3 through 12 of Table 3. Assuming all other factors to be equal, the relative mole ratios in Table 3 reveal that incorrect molecular ion abundance ratios will be observed in all ten mass spectra. The error in the RIAs increases with decreasing mass for a given spectrum and becomes larger as the spectrum number rises for a given mass. Thus, neglecting to account for changes in the composition of the vapor within the reservoir inlet during acquisition of the mass spectra will introduce errors into a quantitative analysis provided that other experimental errors are less than the changes in composition on a percentage basis. Under this assumption, the variations in the mole ratios shown in Table 3 would, unless accounted for, negate the increase in accuracy obtained by averaging the corresponding molecular ion signal magnitudes in the ten scans of the mass spectrum of the mixture.

We now consider the effect of decreasing the cross-sectional area of the leak on the composition of the vapor in the reservoir during acquisition of a mass spectrum at 1000 s/decade rather than at 100 s/decade. For this scan rate, columns 5 and 6 of Table 4 give the moles of each of the seven components relative to the moles of $C_{42}H_{78}$ remaining in the inlet at the times for detection of the corresponding molecular ions calculated for cross-sectional areas of the leak of 2.076×10^{-5} and 7.378×10^{-6} cm^2, respectively. For the purposes of comparison, the values of the remaining parameters in these calculations were identical to those used in calculating the mole ratios in Tables 2 and 3. Comparison of the mole ratios in columns 5 and 6 of Table 4 reveals that a reduction of ca. 64% in the cross-sectional area of the leak significantly reduces the alteration in the composition of the vapor in the inlet during acquisition of the mass spectrum of the mixture. Such a reduction in

the cross-sectional area of the leak significantly reduces the contribution of the mass dependence of effusion across the leak to the error in analysis especially for the lower mass compounds. Since the times for acquiring one spectrum of the mixture at a magnetic field scan rate of 1000 s/decade and ten spectra of the mixture at a magnetic field scan rate of 100 s/decade are very similar, use of the leak with the smaller cross-sectional area would significantly reduce the variation in the relative mole ratios shown in Tables 2 and 3.

4.1.3 Processing of Mass Spectra

The time dependence of the ion signal magnitudes should obey Equation (6). Thus, the errors introduced into an analysis by changes in the composition of the vapor in the inlet during the time required for acquisition of a mass spectrum can be minimized by extrapolating the logarithm of the ion signal magnitudes to zero time. With respect to mass spectra acquired at 100 s/decade for our hypothetical mixture, the quantitative analysis would employ the seven average molecular ion signal magnitudes calculated from the ten zero-time signal magnitudes for each ion which were obtained by a least-squares fit of the individual signal magnitudes in each of the ten spectra to Equation (6). The times listed in column 3 of Table 4 reveal the impracticality of acquiring multiple scans of a mass spectrum at a magnetic field scan rate of 1000 s/decade if the components in a mixture cover a reasonable mass range. A possible approach to minimizing the error in such situations would be to calculate effusion constants for the various components in the mixture using Equation (7). These values and both the arrival times and signal magnitudes of the corresponding ions would be substituted into Equation (6) to arrive at estimated zero-time signal magnitudes for these ions.

An experimental approach to accounting for the mass dependence of effusive flow would be to acquire mass spectra under conditions of constant timing. The mass spectra of samples would be acquired under conditions such that the signal magnitudes of the various ions are recorded at the same time intervals following introduction of each sample into the reservoir inlet. The sensitivities for those ion m/z values to be used in the analyses are either determined at the same time intervals or calculated at these time intervals from values measured at other known time intervals. Consequently, the signal magnitudes of these ions in the spectra of both the mixtures of unknown composition and the calibrating substance or mixture would then be, within the limits of experimental accuracy, the same fractions of their zero-time signal magnitudes. Since the ion signal magnitudes obtained under these conditions are directly used in calculating quantitative distributions, time has been experimentally eliminated as an independent variable. This approach is especially useful in the analysis of mixtures of noncondensable gases.

The aforementioned approaches to accounting for the compositional dependence of ion signal magnitudes are extremely tedious and time-consuming. Thus, a decision regarding implementation of such data analyses should include a consideration of the uncertainties in the ion signal magnitudes and the availability of ionization sensitivities. The accuracy of the ion abundances reflects both the ion statistics and the variation in instrumental parameters governing the generation, extraction, transmission and detection of the ions. The factors which determine the ion statistics for the various m/z values include the amounts of each component charged, the

Table 4 Effect of the cross-sectional area of the leak on the moles of −6(H) series homologs relative to moles of the $C_{42}H_{78}$ −6(H) series homolog comprising a gaseous mixture in a reservoir inlet at 325 °C during acquisition of a 1000 s/decade mass spectrum

Components		Arrival Time for M^+ (s)[a]	Relative moles in reservoir		
Formula	Mass		Initial	at detection of M^+ for cross-sectional area $\times 10^{-5}$ cm^2 of	
				2.076[b]	0.7378[c]

[a] Calculated for exponential scanning from m/z 650 to m/z 70 at 1000 s/decade; i.e. $k_s = 2.3026 \times 10^{-3}$ s^{-1}; 300 s elapsed time between opening leak-line valve and initiation of spectrum acquisition.
[b] Calculated for k_{eff} values in column 3 of Table 2.
[c] Calculate for $k_{eff} \times 10^{-5}$ values of 2.9238, 3.1607, 3.4666, 3.8829, 4.4973, 5.5422 and 7.9882, respectively.

cross-sections for their ionization, and the efficiencies of extraction of ions from the source and of the transmission of ions at a given RP. In this regard, the analysis of multiple scans of the mass spectra obtained from repeated injections of various samples of present interest suggests that a standard deviation of up to about 10% in the molecular-ion relative abundances for components accounting for reasonable weight percentages of the mixtures is not atypical. As discussed later, the situation with regard to the availability of ionization sensitivities and the standard deviations associated with these values is in general unsatisfactory. Based upon these considerations, the mathematical analysis of ion signal magnitudes to account for changes in vapor composition resulting from effusion across a leak is justified in order to obtain highly accurate analysis of mixtures of noncondensable gases. However, such analyses would not in general be warranted for mixtures of condensates given reservoir–inlet system parameters similar to those considered in the present discussion. The mole ratios in Tables 2–4 support this conclusion especially for compounds having masses in excess of ca. 150 amu. Depending upon the accuracy in the ion signal magnitudes, corrections may be justified for lower molecular weight compounds. Finally, the rates of effusion are directly proportional to the cross-sectional area of the leak divided by the volume of the inlet and exhibit a half-power dependence on the absolute temperature divided by the mass of each species. For exponential scanning of the magnetic field, the change in the composition of the vapor in the inlet and, hence, the variation in the relative ion signal magnitudes are exponentially dependent upon the effusion constants and the ion-arrival times. Thus, the effect of compositional changes on accuracy can be minimized by considering the nature of the samples to be analyzed and both the rates for acquiring mass spectra and the functional form of the scan law in developing specifications for a reservoir–inlet system.

4.2 Direct Introduction Probe

The technique of direct-probe introduction of samples into a mass spectrometer ion source has been used in the MS analysis of a variety of fossil fuel materials.[24,28,58,59,62,64,67–69,77,79,89,93,94,105] However, the majority of these studies involved the acquisition of either high-resolution mass spectra for the purpose of determining molecular formulas or low-resolution (unit mass resolved) mass spectra. In only several of these studies were the HRMS acquired both to identify and quantify the homologs present in samples.[62,79,93,94]

4.2.1 Status of Results Obtained Using the Technique

The objectives in using a direct probe rather then an AGHIS for sample introduction are twofold: first, to increase the analyzable molecular weight range because ion-source pressures are most likely to be less than the pressures in reservoir–inlet systems and, second, to reduce any occurrences of thermal decompostions by decreasing the residence time of the gaseous molecules in the system prior to their ionization. In the opinion of the author, the studies reported to date preclude a definite assessment of the extent to which the first objective is attained for various compound classes.

Ions having m/z values ranging from about 100 up to about 1900 were observed in low-resolution FI mass spectra of probe introduced samples obtained from application of molecular distillation and sequential elution fractionation to atmospheric residues.[105] Low resolution FI mass spectra containing ions with m/z values ranging up to about 900–1200 were been obtained from probe distillation of saturated hydrocarbon and aromatic neutral fractions from a petroleum distillate having 50% point AEBPs from about 1050 to 1250 °F (566 to 677 °C).[77] It is unfortunate that the mass spectra in these latter experiments were not also acquired at RPs in the range 10 000–50 000 because ion signal magnitudes, and hence, the analyzable molecular weight range decreases with increasing RP, with the decrease in RP exceeding linearity at RP values greater then 10 000.[83] In this regard, it should be noted that the author has routinely observed ions having low signal magnitudes above m/z 700 in the 40 000 RP LVEI mass spectra of gas–oil–aromatic–neutral fractions introduced into the ion source via a batch inlet at 300–325 °C.

Probe distillation LVEI mass spectra of an aromatic neutral fraction from the 1000–1250 °F (538–677 °C) AEBP distillate of a different crude that were acquired at RPs ranging from 3000–10 000 exhibited ranges of ion m/z values comparable to those that are observed using batch inlet introduction.[62] The same conclusion is indicated to account for probe distillation of the saturates and aromatic neutrals from the maltene fraction of a tar sand bitumen based upon the FI mass spectra and presumably the 70-eV electron ionization (EI) mass spectra obtained at 1000 and 10 000 RP, respectively.[67]

The results from analysis of the 25 000 RP LVEI mass spectra of molten caustic-treated coal extracts indicate that direct probe introduction may increase to some extent the accessible molecular weight range for highly polar compounds containing one or more of the elements N, O and S.[79] However, probe introduction resulted in only about 45% of the pyridine dialysate from one coal being vaporized. Finally, the carbon number ranges of the various hydrocarbon homologous series are consistent with those routinely introduced via a batch inlet.

The technique of probe microdistillation (PMD) was used in analyzing a vanadyl porphyrin fraction isolated from the >700 °C AEBP resid from Venezuelan crude

Cerro Negro. The HRLVEIMS of the volatiles were acquired at 10 000 RP.[94] The mass spectra exhibited ions having m/z values ranging from about 500 to about 850 with the maximum ion signal magnitudes in approximately half of the -28 through -50 $Z(N_4$ VO) series occurring at m/z values less then 700. Approximately two-thirds of the vanadium-containing compounds were found to be distillable.

In the opinion of the author, using the technique of probe introduction to extend the range of analyzable molecular weights of various compound classes significantly requires a detailed study using both a batch inlet and a direct probe to introduce fractions from separation of various fossil fuel materials with the mass spectra acquired over a range of RPs. As discussed below, the issues that attend the incorporation of the technique of probe distillation into HRMS homolog methods would appear to justify such a study.

4.2.2 *Fundamental Considerations in High-resolution Mass Spectrometric Applications*

Since probe distillation of the components of a mixture occurs over a range of temperatures, the pressure of a neutral species in the region of ionization and, hence, the m/z values and signal magnitudes of the corresponding molecular ions observed in mass spectra acquired during a distillation of a sample are temperature dependent. Consequently, quantitative MS employing probe introduction requires the total signal magnitude of the molecular ions detected from the volatilization/ionization of the components as the temperature T_i of the sample in degrees Kelvin is raised from its initial value, T_{int}, to its final value, T_{fin}. The total signal magnitude of the kth molecular ion resulting from volatilization/ionization of the kth component in a mixture is

$$SM(\text{Tot})_k = \int_{T_{\text{int}}}^{T_{\text{fin}}} \text{f}(SM(T)_{k,i})\,\text{d}T \tag{8}$$

One approach to evaluating the integral in Equation (8) is to acquire multiple mass spectra as the probe temperature is raised from its initial to its final value. The signal magnitudes of the corresponding ions in each of the acquired mass spectra are then summed to obtain a total spectrum for distillation of the sample. However, as discussed subsequently, this method for acquiring total molecular ion signal magnitudes is not applicable to the acquisition of HRMS.

When using the technique of probe distillation in performing HRMS-type analyses, Schmidt and Sprecher acquired 25 000 RP LVEI mass spectra of the components of coal extracts that were volatile at four different probe temperatures.[79] Each spectrum at a given temperature was treated as a single analysis and solutions to Equation (8) were obtained by summing the signal magnitudes for the corresponding molecular ions in the spectra acquired at a given probe temperature to obtain a composite spectrum for that temperature. The composite mass spectrum was used to calculate CNDs and other parameters. The fact that this approach entails the acquisition of mass spectra of compounds volatilized at only selected temperatures rather then over the entire temperature range raises a question regarding the extent to which the analytical results represent the actual composition of a sample.

Schronk et al.[62] used the method of PMD developed by Grigsby et al.[119] in the HRMS-type analysis of a monoaromatics fraction from a 1000–1250 °F (538–677 °C) AEBP petroleum distillate. Linear temperature programming at a rate of 7 °C min^{-1} resulted in a distillation time of approximately 28 min. Since 3000 and 10 000 RP mass spectra were acquired using a magnetic field scan rate of 100 s/decade, 25 mass spectra were acquired during a distillation. Variations in the efficiency of extracting ions from an ion source generally occurs during distillations under the condition of linear temperature programming. Since these variations would introduce significant errors into the quantitative results, the ion signal magnitudes are corrected for the occurrence of these variations by acquiring mass spectra containing the signal magnitudes of both the ions from distillation/ionization of a sample and ions $1, 2, 3, \ldots, j$ from ionization of a substance introduced via an expansion volume. The correction factor for the signal magnitudes in the ith mass spectrum acquired at T_i is, Equation (9)

$$CF_i = \frac{\sum_i \sum_j SM_j/N}{\sum_j SM_j} \tag{9}$$

The signal magnitude of the kth ion in the ith mass spectrum corrected for the variation in the ion source extraction efficiency is, Equation (10)

$$SM(\text{cor})_{i,k} = SM(\text{exp})_{i,k} CF_i \tag{10}$$

Equation (11) describes the functional form of $\text{f}(SM(T)_i)$ deduced from an empirical analysis of

$$\text{f}(SM(T)_i) = \frac{A_1 \exp(A_2/T_i)}{1 + \exp[A_3(T_i - A_4)]} \tag{11}$$

the temperature dependence of the ion signal magnitudes resulting from probe distillation of pure compounds.[119] Values of the parameters A_1 through A_4 are obtained from Equation (12) by nonlinear regression analysis

$$SM(\text{cor})_{i,k} = \frac{A_1 \exp(A_2/T_i)}{1 + \exp[A_3(T_i - A_4)]} \tag{12}$$

Figure 8 Elimination curve for PMD of 1-methylnaphthalene. Points correspond to experimental FI ion abundances for m/z 142 at eight temperatures. Curve is calculated from least-squares parameters.

Plots of corrected and least squares predicted signal magnitudes versus absolute temperature are termed elimination curves. As an example, the elimination curve obtained from PMD of 1-methylnaphthalene from a 19 component mixture is reproduced in Figure 8.[64] The dots represent the m/z 158 signal magnitude, temperature pairs. The solid curve corresponds to the least-squares fit of these pairs to Equation (12). Equation (12) is seen to describe accurately the dependence of the m/z 158 signal magnitude on temperature.

The degree of accuracy in CNDs obtained for samples introduced via a direct probe is an important matter that has been inadequately addressed. The results obtained from analyzing mixtures containing 19 and 3 components are, to the author's knowledge, the only ones that directly bear on this matter.[64] Table 5 tabulates the results obtained from the low resolution FI mass spectra of the 19-component mixture with samples introduced via a batch inlet and a direct probe. Column 3 of Table 5 lists the weight percentages of the 19 compounds calculated from weights taken. The results of the original FIMS analysis with sample introduction via a batch inlet are tabulated in columns 4 and 5. Columns 6 and 7 of Table 5 list the corresponding results obtained subsequent to storage of the mixture at 0 °C for two years. Comparison of the weight percents in column 6 with the corresponding values in columns 3 and 4, the corresponding percentage deviations in columns 5 and 7 and both the average errors and associated standard deviations and the root

Table 5 Results obtained from PMD/FIMS and FIMS of 19-component mixture

Mixture			Weight percents and percent deviations with sample introduction by Batch inlet				Direct probe	
Compound	MW	Wt. %	6/76		6/78		6/78

RMS error				±4.2		±9.8		±17.6

FIMS, field ionization mass spectrometric.

mean square (RMS) deviations for the two batch inlet experiments led us to conclude that the mixture was suitable for use in our development of a computer-based method for acquiring and processing probe temperatures and low-resolution mass spectral files.[64] However, the results from the second batch inlet analysis are consistent with the loss of small amounts of the more volatile components indan, 1,3,5-trimethylbenzene and 1,2,3,4-tetrahydronaphthalene during storage and/or handling of the mixture. Also, the variability of the results from this analysis is generally greater then that from the first batch inlet analysis.

Columns 8 and 9 of Table 5 list the weight percentage of each component calculated from the areas under the elimination curves and the percentage deviation in each of these values, respectively. Both the average and RMS errors and the standard deviation in the average error are seen in Table 5 to be larger for the PMD FIMS analysis then for the second batch inlet FIMS analysis. Examination of column 9 reveals that the errors in the PMD FIMS analysis were less then 10% for eight compounds, 10–20% for five compounds and between 20 and 34% for six compounds. The corresponding results from the second batch inlet analysis are 13 compounds, five compounds and one compound, respectively. Thus, at least in this instance, the imprecision in the quantitative results was greater using a direct probe than a batch inlet for sample introduction. The diminished accuracy of the results may be attributed in part to the loss of volatile components upon introduction of the probe into the system and the effect of the rate of temperature increase on the volatilization of these compounds in relation to the time for spectral acquisitions. The values of 33.1%, 22.6% and 44.4% obtained from PMD FIMS analysis of a mixture consisting of 33.2% phenanthrene, 25.1% fluoranthene and 41.7% hexahydropyrene afford a measure of support for this conclusion. These results indicate the need for additional studies using both synthetic blends and fossil-fuel samples with the analytical results for both kinds of samples obtained for both probe and batch inlet introductions in order to establish the ranges in both the accuracy and the precision that are obtainable using direct probe introduction.

Significant problems must be addressed and resolved in order to implement probe introduction HRMS homolog analysis in the molecular weight range were the method(s) would have the most significance, that is, above about mass 400 u for highly polar compounds such as acids and bases and above about 700 u for aromatic neutrals and saturates. In order to begin to define these problems, we consider the probe introduction of the −20(H), −18(H), −16(H) and −32(H) homologs $C_{114}H_{208}$, $C_{114}H_{210}$, $C_{114}H_{212}$ and $C_{115}H_{198}$ under conditions that simulate the presence of these homologs in an aromatic neutral concentrate containing homologs of chemical types ranging in mass from about 750 u to about 1800 u. That is, the amounts of the −20(H), −18(H) and −16(H) homologs to be distilled are equivalent to 0.5 wt% of a 1-mg sample of the aromatic neutral fraction or 3.167×10^{-9}, 3.163×10^{-9} and 3.159×10^{-9} moles; the corresponding values for the −32(H) homolog are 0.05% and 3.163×10^{-10} moles. The LVEI would initially be acquired at 20 000 RP in order to resolve $C_{114}H_{210}$, and $C_{115}H_{198}$, molecular ions having 10 to 1 RIA ratios; see section 6.2. We also assume that: (1) the LVEI mass spectra are characterized by the presence of molecular ions and the absence of fragment ions, (2) the mass spectra are acquired from m/z 1950 to m/z 750 using either a Kratos MS-50 mass spectrometer or an instrument that has a similar dependence of sensitivity on RP with either instrument being fitted with a high-field magnet to permit acquisition of HRLVEIMS at full accelerating voltage, and (3) the magnetic field strength is decayed exponentially at a rate of 300 s/decade with an interscan time of 4 s. The 2000 RP sensitivity for LVEI of phenanthrene is 4.4×10^{17} ions mol^{-1}. The ratio of the sensitivity at 20 000 RP to the sensitivity at 2000 RP is about 0.071. Making the usual assumption that LVEI sensitivities are carbon-number independent results in a 20 000 RP sensitivity for LVEI of $C_{114}H_{210}$ of 3.12×10^{16} ions mol^{-1} and mole sensitivities for −20(H), −32(H) and −16(H) homologs relative to the mole sensitivity for −18(H) homologs of 1.24, 1.84 and 0.67, respectively; see section 7.7. The distributions of $C_{114}H_{208}$, $C_{114}H_{210}$, $C_{114}H_{212}$, and $C_{115}H_{198}$ molecules and, hence, molecular ions containing carbon-13 but not deuterium were calculated as described in section 7.1. Molecules containing from zero through six atoms of carbon-13 were found to account for 99.97% of the −20(H), −32(H), −18(H) and −16(H) neutral and ionic species.

Consider two ions having m/z values such that $(m/z)_2 > (m/z)_1$. For magnetic focusing instruments

$$(m/z)_2 = (m/z)_1(1 + \alpha) \tag{13}$$

The scan law for exponential decay of the magnetic field strength is

$$\ln \frac{(m/z)_2}{(m/z)_1} = -kt \tag{14}$$

where k is the scan law constant in reciprocal seconds and $t_0 = 0$. Combining Equations (13) and (14) and noting that $\alpha = 1/RP$, we obtain Equation (15) for the peak width in seconds as a function of the RP and the rate constant for exponential decay

$$pw_{RP} = \frac{1}{k} \ln \left(\frac{RP}{RP + 1} \right. \tag{15}$$

Equation (14) can be used to obtain a value of k given the time it takes to scan a decade of m/z values, that is, for $t = 300$ s/decade, $k = 7.6753 \times 10^{-3}\ s^{-1}$. Although the actual scan law is not ideal, the author has routinely realized good agreement between theoretically predicted and experimental peak widths at 5% of the peak heights provided that the Kratos MS-50 is set up so that the RP is essentially constant over the range of m/z values being scanned.

Following Schmidt and Sprecher,[79] we assume that probe introduction at temperature T resulted in a constant beam current for 10 min. Since the time for acquiring a spectrum is calculated to be 124.5 s and the interscan time is 4 s, four 20 000-RP LVEI/MS will be acquired during this time interval. For LVEI of each of the $j = 1, 2, \ldots, 7$ isotopically substituted $-20(H)_{i=1}$, $-32(H)_{i=2}$, $-18(H)_{i=3}$, and $-16(H)_{i=4}$ molecules, Equations (16) and (17) were solved to obtain values for the predicted total number of ions and the experimental total number of ions that include estimates of the effects of ion statistics, respectively.

$$N_{i,j} = NOS \times \text{floor}\ \frac{1}{2}\frac{\text{moles}[-Z(H)_i]}{DT}\frac{PA_{i,j}}{100} \times S(\text{mol})_{i=3} RS(\text{mol})_i pw_{RP} \quad (16)$$

$$N\exp_{i,j} = N_{i,j} + \text{floor}(r_{i,j}\sqrt{N_{i,j}}) \quad (17)$$

In Equation (16), NOS is the number of acquired mass spectra, $PA_{i,j}$ are the percentage abundances of the seven isotopically substituted molecules/molecular ions, $S(\text{mol})_{i=3}$ is the mole sensitivity for LVEI of $C_{114}H_{210}$ at 20 000 RP, $RS(\text{mol})_i$ are the relative mole sensitivities for LVEI of $C_{114}H_{208}$, $C_{115}H_{198}$, $C_{114}H_{210}$ and $C_{114}H_{212}$ and DT is the distillation time. In Equation (17), $r_{i,j}$ are sets of random numbers having normal distributions with $\mu = 0$ and $\sigma = 1$. Estimates of the effects of ion statistics on the ion yields were based on the ion sums both for the sake of simplicity and because essentially the same result was obtained from summing the estimates of ion statistics on the ion yields in each of the four spectra for two of the molecules.

The specific Z values, the formulas, and the mass numbers of the various isotopically substituted molecules/molecular ions are listed in columns 2, 3 and 4, respectively, in Table 6. Columns 5 and 6 of Table 6 contain the percentage abundances of $-20(H)$, $-18(H)$ and $-16(H)$ molecules/molecular ions containing 0 through 6 atoms of carbon-13 and $-32(H)$ molecules/molecular ions containing 0 through 5 atoms of carbon-13, respectively. The mass-to-charge ratio and the predicted ion total for each molecular ion are given in columns 7 and 8, respectively. RPs in column 10 were calculated assuming unit RIAs for successive ion beams whereas those in column 11 were calculated for the RIAs in column 9; see section 6.2.

Comparison of corresponding RPs in columns 10 and 11 in Table 6 shows that the relative abundance of successive ion beams can significantly increase the RP required to obtain resolution of successive ion beams. The resolution of a number of successive ions such as 4 and 5, 7 and 8 and 10 and 11 is seen in columns 10 and 11 greatly to exceed the capabilities of state-of-the-art DF mass spectrometers. In this regard, the resolution of $-20(O)$ molecular ions $C_{113}H_{206}O^{+\bullet}$ from $-18(H)$ molecular ions having relative abundances ranging from 1 to 10 would require RPs ranging from about 43 400–50 600. These results together with the discussion in section 6 demonstrate that resolution of many isobaric ions in the "high mass region" will simply not be possible using DF instruments.

Table 7 list the results obtained from processing the composite "experimental" 20 000-RP LVEI/MS from probe distillation of $C_{114}H_{208}$, $C_{115}H_{198}$, $C_{114}H_{210}$ and $C_{114}H_{212}$ at temperature T. The specific Z values and the formulas of the various isotopically substituted molecular ions are listed in columns 2 and 3, respectively. Columns 4 and 5 contain normalized percentage abundances of $-20(H)$, $-18(H)$ and $-16(H)$ molecular ions and $-32(H)$ molecular ions, respectively, calculated from the percentage abundances in Table 6. The m/z values and the predicted ion abundances in Table 6 are shown in columns 6 and 7, respectively. The m/z values and the abundances of the ions in the composite "experimental" spectrum are tabulated in columns 8 and 9, respectively. The following procedure was used to obtain experimental m/z values and abundances for unresolved peaks. Equations (18) and (19) were solved to obtain a m/z value and an experimental ion abundance. Solutions to Equation (19) and the known m/z values for resolved peaks were

$$\text{ions} = \sum_i N_{i,j} \quad (18)$$

$$m/z = \frac{\sum N_{i,j} \times m/z_{i,j}}{\text{ions}} \quad (19)$$

subject to a 5-ppm error multiplied by random numbers having normal distributions with $\mu = 0$ and $\sigma = 1$. The entries in columns 10–13 are the results obtained from deisotoping/formula assignment of the m/z signal magnitude pairs using Equations (18) and (19) as described in Gaun et al.[92]

The mass measurement errors in column 12 are seen to be typical of the values encountered in processing HRLVEIMS in the "conventional" mass range. The

[a] Mass-to-charge measurement error in parts per million, i.e. values in column 6 minus values in column 11 divided by values in column 11 multiplied by 10^6.
[b] Percentage differences between predicted numbers of ions in column 7 and the numbers of ions after deisotoping spectra in column 10.

percentage deviations in the ion abundances in column 13 in relation to the ion abundances in column 9 are similar to the repeatability that can be attained in ion abundances calculated from the signal magnitudes in HRLVEIMS in the ''conventional'' mass range. Subject to a number of considerations, Tables 6 and 7 indicate the desirability of performing well-conceived experiments to assess the feasibility of using probe distillation to extend homolog-type analysis to aromatic hydrocarbon fractions having AEBPs up to about 1400 °F (760 °C). The assumed absence of fragment ions is most likely to be invalid for LVEI. The presence of significant numbers of fragment ions relative to molecular ions would undoubedtly complicate spectral interpretations. For example, hydrogen atom loss from $C_{114}H_{210}{}^+$ would result in the formation of $C_{114}H_{209}{}^+$ with a mass that differs from the mass of the −20(H) ion $^{13}CC_{113}H_{208}{}^{+\bullet}$ by only 4.5 mmu (millimass units). Since deisotoping of the experimental ion abundances will be necessary especially with DF instruments, decisions regarding the composition/origin of the ion masses in a sequence will be required. For example, for Table 7 a decision would have to be made regarding the value of a residual abundance for ion 2 that would be attributed to the presence of $C_{114}H_{209}$ fragment ions rather than to ion statistics and/or variations in the abundance of carbon-13/deuterium. In addition, the loss of two hydrogens or H_2 from $C_{114}H_{210}{}^+$ would result in the formation of $C_{114}H_{208}{}^{+\bullet}$. Thus, a decision would be required

about the extent to which the signal magnitude of the mass 1577.6276 ion reflects the presence of a −20(H) homolog in the sample. This extension of homolog methods would clearly benefit from the implementation/development of ionization techniques resulting in mass spectra characterized by the presence of molecular ions, the essential absence of fragment ions and by the development of separation techniques producing well-defined ring number fractions. Also, FTICR MS could be an important technique in method development given the RPs that have been achieved to date in the LVEI mass spectra of lower boiling petroleum distillates.[91,92,97] Finally, the procedure to be used in calculating CNDs must be addressed. The usual practice in the ''conventional'' mass range is to base the calculation of these distributions on the signal magnitudes of the isotopically most-abundant molecular ions. However, as seen in Tables 6 and 7 the dominance of a distribution of molecular ion signal magnitudes by a single isotopic molecular ion decreases with increasing mass-to-charge ratio.

5 IONIZATION TECHNIQUES: APPLICATIONS

5.1 Low-voltage Electron Ionization

For various reasons LVEI is the principal ionization technique used in the HRMS method for determining group types. (See refs. 6, 8, 10, 11, 13, 15–17, 19–24, 26, 31–35, 37–39, 41, 44, 47, 48, 52, 53, 61, 62, 71, 72, 75, 79, 82, 85, 86, 88, 91–94, 97)

A number of commercial ion sources can be operated at low voltage without significant if any modification in a well maintained and optimally tuned DF mass spectrometer such as the Kratos MS-50 to generate ion beams that are intense enough for the routine acquisition of mass spectra of distillates at RPs ranging up to about 50 000. A number analysts including the author have acquired HRLVEIMS at RPs ranging up to 80 000–100 000.[41] The technique is applicable to neutral, acidic and basic aromatic compound types. However, aromatic carboxylic acids are undoubedtly an exception. For example, the author has normally observed significant numbers of molecular ions phenomenologically corresponding to the ionization of homolgs of various aromatic hydrocarbon types in the HRLVEIMS of acid fractions which are known from ^{13}C NMR (nuclear magnetic resonance) and IR (infrared) spectroscopy to contain carboxylic acids. The LVEI technique is not applicable to saturate fractions.

5.2 Field Ionization

The technique of FI has been shown to be applicable to the mass spectrometric analysis of distillates boiling up to 400 °F (204 °C) and saturate, aromatic neutral, acidic and basic fractions from higher boiling distillates. However, FIMS has not enjoyed wide acceptance for a number of reasons. FI sources are not commercially available for all mass spectrometers. Achieving optimum performance of the source on a routine basis is often tedious and difficult. The majority of FI applications have involved the acquisition of low-resolution spectra.[25,29,36,42,43,46,49,51,54,58,59,64,67–69,74,76,77,89,95,105] With this in mind, it should be noted that unit resolution FI mass spectra suffice for the determination of CNDs for saturate fractions. The technique has found few applications in HRMS homolog analysis. Acquisition of mass spectra with adequate ion abundances using a DF mass spectrometer equipped with an FI source is limited under the best of conditions to RPs of less then about 10 000. One approach to using FIMS to determine CNDs involved a convoluted process.[60,61] FIMS were data system acquired at about 2000 RP and oscillographically recorded at 7500–10 000-RP. The heights of resolved and partially resolved peaks in the latter spectra were hand measured and the nominal m/z values of these ions were interpreted in terms of the formulas assigned to ion m/z values observed in the 20 000 or greater RP 70-eV spectra recorded on photoplates. These results were then used to factor the ion abundances in the 2000 RP FIMS into signal magnitudes for the various homologous molecular ions. Using a Kratos MS-50 equipped with a combination FI/EI ion source, Parisi and Scheppele determined CND for low-boiling distillates from FIMS data system acquired at about 7500 RP.[120] The known masses of +2(H) ions were used to convert the time centroids of the peaks in the spectra to masses.

5.3 Other Ionization Techniques

The techniques of chemical ionization (CI), charge exchange (CE) and fast atom bombardment (FAB) have received consideration as alternative ionization techniques in type analysis. The results as described below indicate the possibility of using one or more of these techniques to circumvent a number of existing problems in HRMS homolog-type analysis.

Veloski et al. reported the acquisition of mass spectra of a coal derived distillate and a petroleum-derived residuum obtained at a static RP of 20 000 with ion formation accomplished using low-pressure ammonia CI and LVEI.[93] The ammonia CI results are especially significant because of the problem, as discussed by both the authors and subsequently in sections 6.3 and 6.4, of resolving ions differing in composition by ^{13}CH/N using DF mass spectrometers. As demonstrated by the CNDs obtained from the chemical ionization high resolution mass spectra (CIHRMS) and the HRLVEIMS for the unfractionated

coal-derived distillate, this resolution problem effectively precludes, in general, the determination of low-levels of $Z(\mathrm{N\ O}_b\ \mathrm{S}_c)$ homologs in samples dominated by $Z(\mathrm{H\ O}_b\ \mathrm{S}_c)$ homologs using LVEI as the ionizing agent.

Allgood et al. found that charge-exchange reactions between $C_6H_6^{\bullet+}$ and series of olefins and alkylbenzenes under CI conditions resulted in mass spectra containing essentially only molecular ions.[81] The dependence of the relative molar sensitivities on molecular structure was found to be less then 10–15%. As expected, CE reactions between $C_6H_6^{\bullet+}$ and alkanes and cycloalkanes were not observed allowing homologs of olefinic and aromatic compound types to be differentiated from homologs of these compound types. Hsu and Qian investigated CE reactions between $CS_2^{\bullet+}$ and a series of aromatic hydrocarbons.[90] Electron beam energies that produced m/z 106 to m/z 91 ratios > 50 : 1 gave CS_2 CE conditions that resulted in maximum ion signal magnitudes and minimum formation of fragment ions. However, the molecular structure dependence of sensitivity is greater for CS_2 CE than for C_6H_6 CE because the increase in the alkyl carbon number from 6 to 13 in the −6(H) series was accompanied by an approximately 67% increase in the CS_2 CE sensitivity. There are indications that an increase in the number of condensed aromatic rings results in a substantial increase in the sensitivity for CS_2 CE of aromatic hydrocarbons, for example, the sensitivity for benzo[*a*]pyrene is about 3.3 times greater then the sensitivity for naphthalene.

Dzidic et al. developed and applied a GC low-resolution mass spectrometric method for hydrocarbon-type analysis of 350–850 °F (177–455 °C) distillates using Townsend discharge nitric oxide chemical ionization (TDNOCI).[87] The NO^+ produced under TDNOCI conditions distinguishes between homologs of hydrocarbon types by the occurrence of: (1) CE reactions with aromatics, (2) hydride extraction reactions with saturates and (3) addition reactions as well as both CE and hydride extraction reactions with olefins.

Dzidic investigated fluoride ion CI low-resolution MS with sample introductions using a direct probe as a method for determining naphthenic acids.[78] Unfortunately the use of a quadrupole instrument precludes the resolution of isobaric carboxylate anions and, hence, the determination of CNDs. Fan reported on the characterization of naphthenic acids using negative ion FAB MS.[84] The 2000 RP FAB spectra obtained from Xe bombardment of acid–triethanolamine matrices consisted of only $(M-H)^-$ ions. In contrast to this result, Grigsby et al. found that the positive ion FAB spectra of nitrogenous compounds and a base fraction from anthracene oil exhibited significant $M^{\bullet+}$, $(M+H)^+$, $(M-H)^+$ and fragment ions.[63]

6 QUALITATIVE ANALYSIS

6.1 Processing of High-resolution Mass Spectra

In general, an experimental high-resolution mass spectrum consists of pairs of data points consisting of peak positions and the sum of the signal magnitudes of the detected ions defining the peaks. The phrase "in general" is used because at least two commercial data acquisition systems afford the capability of storing "raw" data points, that is, the digitized signals from the mass spectrometer and the precisely defined times at which the signals were acquired. Peak positions in spectra acquired using a DF mass spectrometer commonly are the times for the peak centroids calculated from the data points defining the peaks. Peak positions in spectra acquired using a FTICR mass spectrometer are the frequencies of the peak centroids calculated from the frequencies across the peak obtained by fast Fourier transformation of the time-dependent signal from the FTICR instrument. The peak positions expressed as either times or frequencies must be converted to masses.

The time centroids of the peaks in spectra acquired exponentially using DF instruments are converted to highly accurate masses using a polynomial of the form,[66] Equation (20)

$$\ln(m/z) = A + Bt + Ct^2 + Dt^3 \tag{20}$$

The coefficients A–D in Equation (20) are determined by least squares analysis of the time centroids of known masses of five successive ions in a spectrum. A polynomial equation such as Equation (20) is used in place of Equation (14) because, as mentioned in section 4.2.2, Equation (14) is an inexact description of the rate of decrease of the magnetic field strength.

The frequency centroids of the peaks in spectra acquired using a FTICR mass spectrometer can be converted to masses using the relationship in Equation (21)

$$m/z = \frac{a}{\nu} + \frac{b}{\nu^2} \tag{21}$$

which is exact in the limit of a pure quadrupolar electrostatic trapping potential.[92,97] Values of the parameters a and b are determined by least squares analysis of the frequency centroids of known masses of three successive ions in a spectrum.

Concurrent acquisition of the spectrum of both know compounds and the sample being analyzed is one approach to establishing values of the masses and time centroids for determining the parameters in Equations (20) and (21). The mass defects of the reference ions must be considerably larger then those for the ions of unknown composition. Unfortunately, the traditional reference standards used with 70-eV electrons,

such as perfluorokerosenes, are not suitable for use with low-voltage electrons. Thus, mixtures consisting primarily of halogenated compounds have been used as mass calibrants.[33,75,80] However, several problems attend the extensive use of chlorinated and/or brominated aromatic compounds. First, these compounds by their nature contain isotopically substituted molecules that result in the formation of isotopically substituted ions that are not germane to the calibration process. The presence of these molecules restricts the amount of sample that can be charged because the pressure range over which an ion source operates efficiently is necessarily restricted. Second, it has not been possible to achieve an optimum mass difference of approximately 14 u between successive molecular ions especially in the mass region above 300 u. Third, the insolubility of a number of these halogenated compounds complicates the preparation of reference blends. The compounds in Table 8 were adopted as calibrants at the Amoco Research Center in order to overcome several of these problems. It should be noted that solutions can be prepared that contain 26 of the 31 compounds. However, the issue of the lack of mass calibration standards above mass 630 remains to be resolved.

The use of ions formed from compounds in a sample either alone or in conjunction with ions formed from reference compounds is another approach to mass calibration. One caveat in the use of this approach is that the time centroids of the peaks used as reference standards must not have derived significant contributions from unresolved ions.

Schmidt and Sprecher used the mass measurement accuracy obtained from assigning formulas to mass converted peak centroids as a criterion for selecting sample peaks to be used in conjunction with reference peaks.[79] The identification of a number of peaks resulting from the detection of $Z(\mathrm{H})$ molecular ions containing carbon-13 rather then $Z(\mathrm{NO_2})$ molecular ions is one of several results indicating that valid results were obtained in this instance. However, the ubiquitous problem of resolving ions that differ in composition by C_3/SH_4 using DF mass spectrometers would in general preclude the use of sample peaks in mass converting time centroids in mass spectra of samples such as aromatic neutral, acidic and basic fractions that contain significant amounts of sulfur compounds. For example, the $-6(\mathrm{H})$ series is the only homologous series of molecular ion peaks in the HRLVEIMS of aromatic neutrals that does not a priori reflect the detection of ions differing in composition by C_3/SH_4. Hsu et al. have approached the problem by performing ring-number separations of aromatic neutral fractions prior to obtaining HRLVEIMS.[86] At least in principle the ring number separation should significantly mitigate the C_3/SH_4 resolution problem. For example, HPLC separation should place the $-10(\mathrm{S})$ series in the diaromatic fraction and the isobaric $-20(\mathrm{H})$ series in the three-ring fraction. It should be noted when using this approach that the resolution in the separation decreases with increasing boiling point and can exhibit a dependency on the origin and history of the aromatic neutral fraction.

Table 8 Compounds for calibrating mass axis in HRLVEIMS

Compound[a]	Formula[b]	Mass
Hexabromobiphenyl[c]	$C_{12}H_4{}^{79}Br_3{}^{79}Br_3$	627.535 177
Tetraiodothiophene[c]	C_4SI_4	587.589 965
Pentyl 2,3,5-triiodobenzoate	$C_{12}H_{13}O_2I_3$	569.804 975
Butyl 2,3,5-triiodobenzoate	$C_{11}H_{11}O_2I_3$	555.789 325
Propyl 2,3,5-triiodobenzoate	$C_{10}H_9O_2I_3$	541.773 675
Ethyl 2,3,5-triiodobenzoate	$C_9H_7O_2I_3$	527.758 025
Methyl 2,3,5-triiodobenzoate	$C_8H_5O_2I_3$	513.742 375
2,3,5-Triiodobenzoic acid[d]	$C_7H_3O_2I_3$	499.726 725
Triiodoanisole[c]	$C_7H_5I_3$	485.747 460
Octafluorodibromobiphenyl	$C_{12}F_8{}^{79}Br^{81}Br$	455.821 851
Di(pentafluorophenyl)phenyl phosphine (Ultramark 443)	$C_{18}H_5F_{10}P$	441.996 919
Diiodofluorene[c]	$C_{13}H_8I_2$	417.871 547
Diiodotetrafluorobenzene	$C_6F_4I_2$	401.802 560
Diiodonaphthalene[c]	$C_{10}H_6I_2$	379.855 897
Decafluorobenzophenone	$C_{13}F_{10}O$	361.978 947
Perfluorobiphenyl	$C_{12}F_{10}$	333.984 032
Dibromotetrafluorobenzene	$C_6F_4{}^{79}Br^{81}Br$	307.828 239
Iodopentafluorobenzene	C_6F_5I	293.896 490
Octafluoronaphthalene	$C_{10}F_8$	271.987 226
Iodonaphthalene	$C_{10}H_7I$	253.959 249
Fluoroiodotoluene[e]	C_7H_6FI	235.949 827
Iodofluorobenzene[e]	C_6H_4FI	221.934 177
Iodobenzene	C_6H_5I	203.943 599
Hexafluorobenzene	C_6F_6	185.990 419
Pentafluorobenzene	C_6HF_5	167.999 841
Tetrafluorobenzene[e]	$C_6H_2F_4$	150.009 263
Trifluorobenzene[e]	$C_6H_3F_3$	132.018 685
Difluorobenzene[e]	$C_6H_4F_2$	114.028 107
Fluorobenzene	C_6H_5F	96.037 528
Benzene-d_6	C_6D_6	84.084 611
Dimethylformamide	C_3H_7NO	73.052 764

[a] Compounds in solution unless otherwise noted.
[b] C = carbon-12.

[d] Fragment ion.
[e] Isomer not critical.

6.2 Resolving Power: Definitions

RP for magnetic deflection mass spectrometers is conventionally defined as the peak separation $(m/z)_{i+1} - (m/z)_i$ corresponding to a 10% valley between two equal-magnitude peaks resulting from detection of successive ion beams having mass-to-charge ratios $(m/z)_i$ and $(m/z)_{i+1}$:

$$RP(\mathrm{DF/MS}) = \frac{(m/z)_i}{(m/z)_{i+1} - (m/z)_i} = \frac{(m/z)_i}{\Delta(m/z)} \quad (22)$$

RP for ions of mass-to-charge ratio $(m/z)_i$ is conventionally defined in FTICR MS as

$$RP(\text{FTICR/MS}) = \frac{(m/z)_i}{\Delta(m/z)} \tag{23}$$

where $\Delta(m/z)$ is the full magnitude-mode mass spectral peak width at half-maximum peak height for an isolated peak.

Both definitions depend on peak shape. However, it is important to note that neither definition considers the dependence of peak separation and, hence, RP on the ratio of the signal magnitudes of adjacent peaks. Unfortunately, equal magnitude peaks are clearly the exception rather then the rule. Thus, the RP required to observe resolution of the majority of successive ion beams in the HRMS spectra of most samples exceeds values obtained from Equations (22) and (23) with the RP required to resolve successive ion beams increasing without limit as the ratio of the larger to smaller signal magnitude continues to increase. Therefore, let r be the ratio of the signal magnitudes SM_i and SM_{i+1} of successive beams calculated such that $r \geq 1$, i.e $r = 1$ if $SM_i = SM_{i+1}$, $r = SM_i/SM_{i+1}$ if $SM_i > SM_{i+1}$ and $r = SM_{i+i}/SM_i$ if $SM_{i+1} > SM_i$. Then for mass spectral peak shapes adequately described as Gaussian the dependence of RP on $(m/z)_i$, $\Delta(m/z)$ and r can be shown to be[121]

$$RP = \frac{(m/z)_i}{2\Delta(m/z)} \quad 1 + \sqrt{\frac{\ln(20r)}{\ln 20}} \tag{24}$$

In Equation (24), it is understood that the peaks resulting from detection of successive ion beams are by definition resolved if the valley height is 10% of either peak height if $r = 1$ and if the valley height is 10% of the lower magnitude peak if $r > 1$. Alternatively, ion beams i and $i + 1$ are said to be resolved if the signal magnitudes at the intersection point of the two peak profiles are 5% of either peak height if $r = 1$ or 5% of the lower magnitude peak if $r > 1$. For Gaussian-shaped peaks it should be noted that the RP defined by Equation (23) is about 2.08 times greater then the RP defined by Equation (22).

6.3 Dependence of Resolving Power on the Differences in Composition, Mass-to-charge Ratios and Relative Abundances of Successive Ion Beams

The RP that is appropriate for an HRMS group-type analysis depends in part on the differences in the m/z values and the relative abundances of the isobaric ions that will be present in the mass spectra of a given sample. The difference in ion m/z values resulting from different ion compositions has been considered by a number of individuals.[14,26,50,52,55,57,65,122,123] Table 9 lists differences in ion m/z values for various compositional differences consistent with the general formula $C_nH_xN_aO_bS_c$ and the observation that the coefficients of the heteroatomic species of present interest will in general have values $0 \leq a \leq 2$, $0 \leq b \leq 4$ and $0 \leq c \leq 2$.[65]

The dependence of the m/z values of resolved ion beams having equal signal magnitudes on both RP and the m/z differences between them is illustrated in Figures 9 and 10 for RPs from 10 000 to 80 000 and $\Delta(m/z)$ values from 2×10^{-3} to 30×10^{-3} u. Figures 9 and 10 show that the range of ion m/z values that can be resolved using RP values ranging from 10 000–80 000 exhibits a strong dependence on the difference in m/z values between successive ions. For example, Figures 9 and 10 show that increasing $\Delta(m/z)$ from 2 to 10 to 30 millimass units (mmu) increases the resolvable range of m/z values from 200 to 800 to greater than 1800. The rate of increase in the m/z value of resolved ion beams at a given RP is seen to increase dramatically with increasing $\Delta(m/z)$. For example, Figures 9 and 10 reveal that the upper limit of the mass range of resolved ions at 40 000 RP increases from 80 to 720 as $\Delta(m/z)$ varies from 2 to 18 mmu. However, Figure 9 shows that increasing the RP to 80 000 has only a marginal effect on the resolvable mass range for ions having $\Delta(m/z)$ differences less then 6 mmu.

The dependence of the RP required to resolve doublets on both the ion compositions and relative abundances are illustrated for a range of $\Delta(m/z)$ values in Table 10. Column 4 lists the $\Delta(m/z)$ values resulting from the compositional differences in column 3 between the doublets having the compositions shown in column 2. Values of the RP required for resolution of the members of each doublet having equal signal magnitudes and the maximum m/z value at which each doublet will be resolved are listed in columns 5 and 6, respectively. Inspection of Equation (24) reveals that the relative abundance of resolved ions increases with decreasing m/z at a given RP. The values in columns 7 and 8 in Table 10 illustrate the dependence of the relative abundance of resolved ions on ion mass for the RPs in column 5. For example, a RP of 6438 is predicted to resolve -26(H) and -12(H) ions having relative abundances ≥ 50 at m/z values ≤ 480 and ≥ 100 for $m/z \leq 466$. Table 10 illustrates the ubiquitous problem of resolving ions that differ in composition by C_3/SH_4 and various isotopically substituted ions.

6.4 Mass Analyzers and the Resolution of Ion Beams

6.4.1 Double Focusing Magnetic Instruments

Large geometry state-of-the-art DF instruments can be used to acquire HRLVEIMS exhibiting adequate ion intensities from about m/z 100 to about m/z 650 at RPs ranging up to about 60 000, depending upon factors such as the magnitude of the total aberrations,

Table 9 Differences in compositions and m/z values between successive ions

[a] The mass difference is the absolute value of the difference $(m/z)_2 - (m/z)_1$ for the formula differences F_2/F_1.

Figure 9 Mass-to-charge ratios of resolved ion beams having equal signal magnitudes as a function of RP and mass-to-charge ratio differences of 2×10^{-3}, 6×10^{-3} and 10×10^{-3} u.

Figure 10 Mass-to-charge ratios of resolved ion beams having equal signal magnitudes as a function of RP and mass-to-charge ratio differences of 14×10^{-3}, 18×10^{-3}, 22×10^{-3}, 26×10^{-3} and 30×10^{-3} u.

which for a given instrument determines the ion source and collector slit widths required,[83] the rates of ion production that can be achieved with commercial electron impact sources operated at low voltage, the ranges in both the masses and the amounts of the compounds in a sample and the amount of sample that can be introduced into a DF mass spectrometer ion source. If we assume that singly charged ions having unit relative abundances are to be resolved at mass 650 then ions having compositional differences resulting in mass differences greater then 65, 32.5. 16.3 and 10.8 mmu will be resolved in spectra acquired at 10 000, 20 000, 40 000 and 60 000 RP, respectively. Doublets with mass differences less then these values will not be resolved over the entire mass range. For example, resolution of doublets 22–65 listed in Table 9 should be realized in LVEI mass spectra acquired at 40 000 RP. However, doublets such as $^{13}C/CH$ and C_4/H_2NO_2 (numbers 6 and 14 in Table 9) will be resolved up to m/z values of only about 180 and 344.

The presence of unresolved doublets must be taken into account in the processing of HRLVEIMS in order to avoid introducing significant errors into the analytical results. For example, the signal magnitudes of odd mass peaks potentially corresponding to unresolved $^{13}CH/N$ doublets need to be corrected for contributions from the ion abundances of the appropriate peak at one mass lower in order to avoid overestimating the contribution of nitrogenous homologs to the sample. Failure to consider that odd mass peaks correspond to unresolved $^{13}C/CH$ doublets could result in the erroneous identification of homologs of types such as $Z(NO_2)$ in a sample rather than homologs of fragment ion types such as $Z(H)$ in a spectrum.

A number of indirect approaches to circumventing this lack of spectral resolution have been developed. One approach involves extrapolations based upon a combination of differences in the initial carbon numbers of unresolved molecular ions and the distillation characteristics of their precursor homologs.[35] Unfortunately a detailed description has apparently never been published. Deconvolution of peaks derived from data discreetly acquired during a scan is another approach to enhancing resolution.[56,57,124] The deconvolution method described

Table 10 Dependence of RP on the compositional difference between successive ion beams and on the relative beam intensities

$-Z$	Formula	Difference in		RP for $r = 1$	m/z at which $r = 1$	m/z at which $r =$

by Van Katwijk[56,57] is directly applicable to the processing of spectra acquired by exponential variation of the magnetic field strength. A method developed by Scheppele and Nutter analyses a HRMS for the presence of unresolved peaks, corrects the spectrum for contributions of ions containing either carbon-13 or sulfur-34 or both and assigns probable formulas to the mass and intensity corrected peaks. The method has been described in detail by Gaun et al.[92] A related approach to processing unresolved peaks has been described by Roussis.[98]

6.4.2 Fourier Transform Ion Cyclotron Mass Spectrometers

As seen in Figures 9 and 10, in Table 10 and discussed in section 6.3, resolution of a number of important doublets requires RPs that exceed the capabilities of DF instruments. The instrumental resolution of doublets such as C_3/SH_4, $^{13}C/CH$ and $^{13}CH/N$ would significantly benefit HRMS-type analyses by increasing the reliability of the results and significantly reducing the time for spectral processing. It is thus important to note that several authors have demonstrated the resolution of such doublets in the mass spectra of samples of interest using FTICR mass spectrometers.[91,92,97] In addition, the errors in mass measurement were typically 1 ppm or less.[92,97] The mass range over which spectra exhibiting resolutions exceeding 300 000 (based upon the Full Width Half Maximum (FWHM) definition) can be acquired was significantly increased and, hence, the time required to cover the complete mass range of a sample was diminished by replacement of the three Telsa magnet[92] with a 5.6 Telsa magnet.[96,97]

7 QUANTITATIVE ANALYSIS

Cross-sections for ionization are of fundamental significance to quantitative MS because they provide the basis for describing the relationship between the total ionization and the concentration of neutral species in the region of ionization. However, the relationship between ion signal magnitudes and the composition of a mixture uses the concept of sensitivity. The relationship between cross-sections and sensitivities for EI is developed in sections 7.1 and 7.2 in order to provide a precise definition and a clear understanding of the concept of sensitivities. Formulas for calculating CNDs and a number of chemical properties from these distributions are derived in section 7.3. The effect of isomers on the quantitation of homologs is also addressed. Ionization sensitivities are an important factor in determining the accuracy of CNDs. However, the published literature contains only a limited number of studies involving the determination of low-voltage EI sensitivities for ionization of aromatic compounds.[6,8,10,11,13,16,19,22,23,26,34,37,38,47,72,80,97,125–127] Moreover, few attempts at developing correlations that express the functional dependence of LVEI sensitivities on molecular structure quantitatively have been

reported.[6,8,11,16,20,26,72] Development of these correlations is essential in order to predict values for LVEI sensitivities because the number of organic compounds for which LVEI sensitivities can be determined comprises an unacceptably small subset of the compounds either known or thought to be present in distillates of present interest. Qualitative correlations of the dependence of LVEI sensitivities on molecular structure have been published and extensively reviewed.[35,38,80] Unfortunately, these correlations do not allow the prediction of LVEI sensitivities. Consequently, the following approach was adopted in addressing the issue of developing a database of LVEI sensitivities. Fundamental phenomena that affect the shape of the ionization efficiencies in the threshold region are reviewed in section 7.4. The practical consequences of these phenomena on experimental LVEI ion abundances are considered in section 7.5. Section 7.6 addresses the prediction of LVEI sensitivities from EI and photoionization cross-sections. The reproducibility of sensitivities for LVEI of aromatic hydrocarbons are reviewed and discussed in terms of values predicted from relative electron-impact ionization probabilities assuming a linear threshold law for ionization in section 7.7.

7.1 Electron Ionization Cross-sections

Total ionization cross-sections can be calculated from total ion currents determined without mass analysis of the ion beams. Consider compound k with an internal energy defined by temperature T. Values of the total cross-section for ionization of compound k by electrons with an energy V electron volts are given by Equation (25)

$$\sigma_{k,T,V} = \frac{TIC_{k,T,V}}{(n_{\text{tot},k})\text{Vol}^{-1} I_e d} \tag{25}$$

where $TIC_{k,T,V}$ is the total ion current, I_e is the ionizing electron current, d is the ionizing pathlength in cm and $n_{(\text{tot},k)}\text{Vol}^{-1}$ is the number of molecules per cubic centimeter in the ion source. Thus, the cross-section has units of cm^2 molecule^{-1}.

The cross-sections for ionization of the isotopically most abundant molecules of a given compound are of interest because the m/z values and signal magnitudes of the isotopically most abundant molecular ions rather then total ion signal magnitudes are of analytical significance. If $k(1), k(2), k(3), \ldots, k(l)$ designates the order of the variously isotopically substituted molecules of compound k according to decreasing natural abundance, then the number of each of them is $n[k(1)], n[k(2)], n[k(3)], \ldots, n[k(l)]$. If EI of the isotopically most-abundant molecules results in the formation of molecular ($j = 1$) and fragment ($j = 2, 3, 4, \ldots, m$) ions then the cross-section for ionization of the isotopically most-abundant molecules of compound k is given by Equation (26)

$$\sigma_{k(1),T,V} = \sum_{j=1}^{m} \frac{SM(j)_{k(1),T,V}}{PM(j)_{k(1)} GM(j)_{k(1)} n_{k(1)} \text{Vol}^{-1} I_e d R_r SM_v} \tag{26}$$

In Equation (26), the numerator is the signal magnitude of the jth isotopically most-abundant ion formed from ionization of compound $k(1)$ in volts, $PM(j)_{k(1)}$ represents the probability that the jth ion from $k(1)$ will exit the ion source and be transmitted through the mass analyzer and be detected, $GM(j)_{k(1)}$ designates the detector gain for this ion and R_r and SM_v designate the resistor in the ion-current amplifier and the experimental ion signal magnitude per volt of signal from the detector system, respectively.

We now express the number of isotopically most-abundant molecules $n_{k(1)}$ as a function of the total number of moles of compound k, $N_{\text{tot},k}$. The number of isotopically most-abundant molecules is given by Equation (27)

$$n_{k(1)} = FP_{k(1)} N_{\text{tot},k} N_{\text{A}} \tag{27}$$

where $FP_{k(1)}$ is the fractional percentage abundance of the isotopically most-abundant molecules and N_{A} is Avogadro's number. Values of $FP_{k(1)}$ can be obtained to acceptably high levels of accuracy from Equation (28)

$$FP_{k(1)} = \prod_i \frac{a_{(i)}!}{\prod_j b_{(i,j)}!} \prod_j FP(b_{i,j})^{b(i,j)} \tag{28}$$

where a_i represent the number of the ith element and $b_{i,j}$ denotes the number of the jth isotope of the ith element in a formula. The symbols and values for i and j are defined in terms of elements and isotopes in Table 11.

Table 11 Definition and values of parameters on the right hand side (RHS) of Equation (28)

Substituting Equation (27) into Equation (26), we obtain the following expression for the cross-section for ionization of the isotopically most-abundant molecules of compound k expressed as a function of the signal magnitudes of the molecular ion and fragment ions formed from ionization of molecules $k(1)$, the total moles of compound per cubic centimeter of the ion source, the ionizing electron current, the ionizing pathlength, the detector gain and the probability that a molecular ion will exit the ion source and be transmitted through the mass analyzer and be detected, Equations (29) and (30)

$$\sigma_{k(1),T,V} = \frac{1}{\kappa}\sum_{j=1}^{m}\frac{SM(j)_{k(1),T,V}}{PM(j)_{k(1)}GM(j)_{k(1)}FP_{k(1)}N_{\text{tot},k}} \quad (29)$$

where

$$\kappa = R_r SM_v N_A I_e d\text{Vol}^{-1} \quad (30)$$

The total cross-section for ionization of compound k by electrons possessing energy V is a linear combination of the cross-sections for ionization of the various isotopically substituted species weighted by their fractional percentage abundance, that is, Equation (31)

$$\begin{aligned}\sigma_{k,T,V} &= (\sigma_{k(1),T,V})FP_{k(1)} + (\sigma_{k(2),T,V})FP_{k(2)} + (\sigma_{k(3),T,V}) \\ &\quad \times FP_{k(3)} + (\sigma_{k(4),T,V})FP_{k(4)} + \cdots + (\sigma_{k(m)})FP_{k(m)} \\ &= \sum_{l}(\sigma_{k(l),T,V})FP_{k(l)} \end{aligned} \quad (31)$$

Since the Born–Oppenheimer approximation is valid for the range of energies of present interest, the potential energy hypersurfaces for both ionic and neutral species are independent of isotopic substitution. However, ionization cross-sections could be subject to isotope effects because the vibrational and rotational energy levels associated with these electronic states are isotope dependent. In this regard, the ionization cross-sections for small deuterated polyatomic molecules were subject to deuterium isotope effects ranging from about 1.01 to about 1.05.[128,129] Deuterium and heavy atom such as carbon-13 isotope effects would be expected to be considerably smaller for large polyatomic molecules. Thus, Equation (31), reduces to Equation (32)

$$\sigma_{k,T,V} = (\sigma_{k(1),T,V}) \quad (32)$$

for the condition that isotope effects on ionization cross-sections are less than the experimental uncertainties in these values.

7.2 Low-voltage Ionization Cross-sections and Ionization Sensitivities

In order to derive the relationship between LVEI cross-sections and sensitivities we separate the RHS of the equation obtained from combining Equations (29) and (32) into terms for molecular and fragment ions and rearrange the result to obtain

$$\begin{aligned}(\sigma_{k,T,V})FP_{k(1)} &= \frac{SM(1)_{k(1),T,V}}{\kappa PM(1)_{k(1)}GM(1)_{k(1)}N_{\text{tot},k}} + \frac{1}{\kappa} \\ &\quad \times \sum_{j=2}^{m}\frac{SM(j)_{k(1),T,V}}{PM(j)_{k(1)}GM(j)_{k(1)}N_{\text{tot},k}}\end{aligned} \quad (33)$$

If the cross-section for ionization of compounds by low-voltage electrons are either known or assumed to be dominated by molecular ions then the second term in the RHS of Equation (33) can be neglected. For either situation, Equation (33) reduces to

$$(\sigma_{k,T,V})FP_{k(1)} = \frac{SM(1)_{k(1),T,V}}{\kappa PM(1)_{k(1)}GM(1)_{k(1)}N_{\text{tot},k}} \quad (34)$$

The RHS of Equation (34) is the signal magnitude for the isotopically most-abundant molecular ion for a given value of the concentration of the precursor homolog in the ion source, the ionizing electron current, the ionizing pathlength and both the detector gain and the ion-source extraction and analyzer transmission probabilities for these ions. Thus, a solution of Equation (34) is by definition a mass spectrometric response factor, termed an ionization sensitivity, for the kth compound. Thus, the sensitivity for ionization of the kth compound per mole of the kth compound by low-voltage electrons with energy V, termed the mole sensitivity, has the units square centimeters per mole and is by definition

$$S(\text{mol})_{k,T,V} = \frac{SM(1)_{k(1),T,V}}{\kappa PM(1)_{k(1)}GM(1)_{k(1)}N_{\text{tot},k}} \quad (35)$$

Combining Equations (34) and (35) we obtain

$$S(\text{mol})_{k,T,V} = (\sigma_{k,T,V})FP_{k(1)} \quad (36)$$

Equation (36) reveals that the mole sensitivities required for calculating CNDs from molecular ion signal magnitudes could be obtained from total ionization cross-sections provided that the contribution of fragment ions to the total ionization is either minimal or known.

As discussed in sections 7.4 and 7.5 the ionization cross-section is a rapidly changing function in the threshold region. Consideration of Equations (25), (26) and (35) in terms of this fact and other factors such as the performance characteristics of conventional electron ion sources, the focusing of ion beams and the ion statistics accounts for the difficulties that are often experienced in obtaining satisfactorily reproducible ionization efficiency curves and absolute values of cross-sections and mole sensitivities in the threshold region. The influence of these factors can be minimized by determining relative

cross-sections and relative mole sensitivities. These values can be converted to absolute values given the value for the reference compound. It should be noted that the use of relative rather then absolute mole sensitivities expedites the determination of CNDs because the necessity of determining the absolute sensitivity a mass spectrometer routinely is abrogated.

Let $\sigma_{\mathrm{rel},k,T,V}$ and $\mathrm{S(mol)}_{rel,k,T,V}$ designate the cross-section and mole sensitivity, respectively, for ionization of the kth compound relative to the corresponding quantities for ionization of the reference compound ref, where T and V designate the gas temperature and the ionizing energy, respectively. Let ref(1) represent the isotopically most-abundant neutral and ionic reference species. Thus, the relative cross-sections and relative mole sensitivities are, Equations (37), (38) and (39)

$$\sigma_{\mathrm{rel},k,T,V} = \frac{TIC_{k,T,V}}{TIC_{\mathrm{ref},T,V}} \frac{N_{\mathrm{tot,ref}}}{N_{\mathrm{tot},k}} \tag{37}$$

$$\sigma_{\mathrm{rel},k,T,V} = \frac{SM(1)_{k(1),T,V}}{SM(1)_{\mathrm{ref}(1),T,V}} \frac{N_{\mathrm{tot,ref}}}{N_{\mathrm{tot},k}} \frac{PM(1)_{\mathrm{ref}(1)}}{PM(1)_{k(1)}} \times \frac{GM(1)_{\mathrm{ref}(1)}}{GM(1)_{k(1)}} \frac{FP_{\mathrm{ref}(1)}}{FP_{k(1)}} \tag{38}$$

$$S(\mathrm{mol})_{\mathrm{rel},k,T,V} = \frac{SM(1)_{k(1),T,V}}{SM(1)_{\mathrm{ref}(1),T,V}} \frac{N_{\mathrm{tot,ref}}}{N_{\mathrm{tot},k}} \frac{PM(1)_{\mathrm{ref}(1)}}{PM(1)_{k(1)}} \times \frac{GM(1)_{\mathrm{ref}(1)}}{GM(1)_{k(1)}} \tag{39}$$

Equation (40) expresses relative sensitivities on a gram basis as function of molecular ion signal magnitudes and the grams of each compound in the mixture, $g_{\mathrm{tot},k}$, and the grams of the reference compound, $g_{\mathrm{tot,ref}}$

$$S(\mathrm{g})_{\mathrm{rel},k,T,V} = \frac{SM(1)_{k(1),T,V}}{SM(1)_{\mathrm{ref}(1),T,V}} \frac{g_{\mathrm{tot,ref}}}{g_{\mathrm{tot},k}} \frac{PM(1)_{\mathrm{ref}(1)}}{PM(1)_{k(1)}} \times \frac{GM(1)_{\mathrm{ref}(1)}}{GM(1)_{k(1)}} \tag{40}$$

Relative mole sensitivities are converted into relative gram sensitivities using Equation (41)

$$S(\mathrm{g})_{\mathrm{rel},k,T,V} = S(\mathrm{mol})_{\mathrm{rel},k,T,V} \frac{(M_r)_{\mathrm{ref}}}{(M_r)_k} \tag{41}$$

where $(M_r)_{\mathrm{ref}}$ and $(M_r)_k$ are the relative molecular masses of the reference compound and compound k, calculated from the atomic weights of their constituent elements, respectively.

7.3 Calculation of Carbon Number Distributions and Chemical Properties

Consider the ionization of the jth homolog in the ith specific Z series at temperature T by electrons of voltage V. The jth homolog may consist of 0, 1, 2, 3, . . . , l isomers. For the sake of simplicity, the notation for this homolog is taken to be $Z_{i,j,l}$ and is illustrated in Table 12 for the first three members of the −6(H) homologous series.

Consider a sample containing the four compounds shown in Table 12. The first and second homologs consist of only one compound each. However, the third homolog is composed of four isomers. Following conventional practice, we assume that the detector gains and the ion-source extraction/analyzer transmission probabilities are the same for the molecular ions of the compounds listed in Table 12. Thus, using absolute rather then relative sensitivities, the number of moles of the first and second homologs benzene and toluene are, Equations (42) and (43)

$$N_{\mathrm{tot},Z_{-6,1,0}} = \frac{SM(78)_{Z_{-6,1,0},T,V}}{S(\mathrm{mol})_{Z_{-6,1,0},T,V}} \tag{42}$$

and

$$N_{\mathrm{tot},Z_{-6,2,0}} = \frac{SM(92)_{Z_{-6,2,0},T,V}}{S(\mathrm{mol})_{Z_{-6,2,0},T,V}} \tag{43}$$

respectively. Since the third homolog consists of four isomers, the number of moles of this homolog is given by Equation (44)

$$N_{\mathrm{tot},Z_{-6,3,4}} = \frac{SM(106)_{Z_{-6,3,1},T,V}}{S(\mathrm{mol})_{Z_{-6,3,1},T,V}} + \frac{SM(106)_{Z_{-6,3,2},T,V}}{S(\mathrm{mol})_{Z_{-6,3,2},T,V}} + \frac{SM(106)_{Z_{-6,3,3}}}{S(\mathrm{mol})_{Z_{-6,3,3}}} + \frac{SM(106)_{Z_{-6,3,4}}}{S(\mathrm{mol})_{Z_{-6,3,4}}} \tag{44}$$

Molecular ion mass-to-charge ratios and signal magnitudes are the experimentally accessible quantities in a HRMS homolog analysis. Since the first and second −6(H) homologs correspond to the presence of only one compound each, Equations (42) and (43) can be solved to obtain values for the number of moles of benzene and toluene in the mixture. In contrast, solving Equation (44) to obtain the number of moles of the third −6(H) series homolog would require the signal magnitudes of the four

Table 12 Compounds illustrating nomenclature used in Equations (42–45)

Values of			Compound	Formula	Mass number
i	j	l			
−6	1	0	Benzene	C_6H_6	78
−6	2	0	Toluene	C_7H_8	92
−6	3	1	Ethylbenzene	C_8H_{10}	106
−6	3	2	*o*-Xylene	C_8H_{10}	106
−6	3	3	*m*-Xylene	C_8H_{10}	106
−6	3	4	*p*-Xylene	C_8H_{10}	106

C_8H_{10} molecular ions rather then the sum of these signal magnitudes which is the experimentally accessible quantity $SM(106)_{\exp,T,V}$. Therefore, a homolog mole sensitivity which is a value bounded by the least and greatest mole sensitivities for the set of isomers is substituted for the four sensitivities in Equation (44) in order to obtain a value for the number of moles of the third homolog. Hence, Equation (44) reduces to Equation (45)

$$N_{\text{tot},Z_{-6,3}} = \frac{SM(106)_{\exp,T,V}}{S(\text{mol})_{Z_{-6,3},T,V}} \tag{45}$$

The sensitivities used in calculating quantitative distributions are, in general, values for homologs rather then values for specific compounds. The magnitudes of the error so introduced into the quantitative results are a complex function of variables such as the difference between the assumed and correct sensitivity values for the actual isomeric mixture, the signal magnitude of the homolog molecular ion, the effect of mass discrimination on the molecular-ion signal magnitudes and the number of homologs of the compound types present in the sample.

For the general case, consider a distillate sample containing 1, 2, 3, . . . , *i* compound types. Each compound type consists of 1, 2, . . . , *j* homologs. The mole percentage of the *j*th homolog in the *i*th specific *Z* series is

$$MP_{Z_{i,j}} = \frac{N_{\text{tot},Z_{i,j}}}{\sum_i \sum_j N_{\text{tot},Z_{i,j}}} \times 100 \tag{46}$$

where for the sake of simplicity $Z_{i,j}$ has been substituted for notation $Z(N_aO_bS_c)$. Generalizing the result obtained from substituting Equations (42), (43) and (45) into Equation (46), we obtain Equation (47) for calculating mole-percentage CNDs from the signal magnitudes of the isotopically most-abundant molecular ions

$$MP_{Z_{i,j}} = \frac{(SM_{Z_{i,j},T,V})/(S(\text{mol})_{\text{rel},Z_{i,j},T,V})}{\sum_i \sum_j (SM_{Z_{i,j},T,V})/(S(\text{mol})_{\text{rel},Z_{i,j},T,V})} \times 100 \tag{47}$$

Weight-percentage CNDs can be calculated by solving Equation (48)

$$WP_{Z_{i,j}} = \frac{(SM_{Z_{i,j},T,V})/(S(\text{g})_{\text{rel},Z_{i,j},T,V})}{\sum_i \sum_j (SM_{Z_{i,j},T,V})/(S(\text{g})_{\text{rel},Z_{i,j},T,V})} \times 100 \tag{48}$$

or from mole percentage CNDs using Equation (49)

$$WP_{Z_{i,j}} = \frac{MP_{Z_{i,j}}(M_r)_{Z_{i,j}}}{\sum_i \sum_j MP_{Z_{i,j}}(M_r)_{Z_{i,j}}} \times 100 \tag{49}$$

where $(M_r)_{Z_{i,j}}$ is the relative molecular mass of the *j*th homolog in the *i*th specific *Z* series. CNDs on a weight-percentage basis can also be obtained using Equation (50)

$$WP_{Z_{i,j}} = \frac{[(SM_{Z_{i,j},T,V})/(S(\text{mol})_{\text{rel},Z_{i,j},T,V})] \times (M_r)_{Z_{i,j}}}{\sum_i \sum_j [(SM_{Z_{i,j},T,V})/(S(\text{mol})_{\text{rel},Z_{i,j},T,V})] \times (M_r)_{Z_{i,j}}} \times 100 \tag{50}$$

Aczel and Lumpkin have demonstrated the routine calculation of a significant number of chemical properties from CNDs.[35,52,53] The properties calculated include the average carbon number, the average molecular weight and the elemental analysis for each compound type and for the sample. In addition to these properties, Schmidt et al. reported calculating average specific *Z* values and values of f_a, that is, the fraction of the total carbon that is aromatic.[75] Aczel and Lumpkin have also shown that CNDs can be used to calculate distillation characteristics for a sample and to generate CNDs for the compound types expected to be present in the predicted narrow-boiling distillate cuts.[32] Unfortunately many of the essential details of the method have not been described. Chemical properties for narrow boiling distillate cuts should be predictable from the CNDs for these fractions. Scheppele and Greenwood were able to draw conclusions concerning the occurrence of reaction networks in the hydrotreating of anthracene oil from the CNDs for the feed and products.[60]

In regard to such calculations, the average relative molecular mass for a specific *Z* series, $(\overline{M}_r)_{z_i}$, the average relative molecular mass for the sample, $\overline{M}_r$, the average carbon number for a specific *Z* series, $\bar{n}_{Z_i}$, and the average carbon number for the sample, $\bar{n}$, are solutions to Equations (51–54), respectively

$$(\overline{M}_r)_{Z_i} = \frac{\sum_j MP_{Z_{i,j}}(M_r)_{Z_{i,j}}}{TMP_{Z_i}} \tag{51}$$

$$\overline{M}_r = \frac{\sum_i TMP_{Z_i}(\overline{M}_r)_{Z_i}}{100} \tag{52}$$

$$\bar{n}_{Z_i} = \frac{\sum_i MP_{Z_i} n_{Z_i}}{TMP_{Z_i}} \tag{53}$$

$$\bar{n} = \frac{\sum_i TMP_{Z_i}\bar{n}_{Z_i}}{100} \tag{54}$$

where, Equation (55)

$$TMP_{Z_i} = \sum_j MP_{Z_{i,j}} \tag{55}$$

Let Y_u denote the presence of u atoms of element Y in a formula and let $A(Y)$ represent the atomic weight of element Y. The weight percentage of element Y in a sample is thus

$$WP(Y) = A(Y) \sum_i \sum_j \frac{WP_{Z_{i,j}} u_{Z_{i,j}}}{(M_r)_{Z_{i,j}}} \quad (56)$$

where $(M_r)_{Z_{i,j}}$ is the relative molecular mass of a homolog calculated from the atomic weights of its constituent elements.

7.4 Fundamental Phenomena

Consider compound k with an internal energy defined by temperature T. The cross-section for its ionization by electrons having a nominal energy V is given by

$$\sigma_{k,T,E} = \sum_K \int_{-\infty}^{+\infty} K_\kappa Th(V - IP_\kappa)^w m(V - IP_\kappa)\,dV \quad (57)$$

where K_κ are the probabilities for transitions from the ground state of the neutral molecule to the various κ states of the ion having ionization potentials IP_κ, $Th(V - IP_\kappa)^w$ are the threshold laws for the transitions and $m(V - IP_\kappa)$ is the energy distribution in the ionizing beam.[130–132] Equation (57) includes contributions of single-direct ionization, multiple-direct ionization and autoionization to the cross-section. The contribution of multiple-direct ionization to the cross-section for ionization in the threshold region should be negligible for compounds of present interest. Unfortunately, very little definitive evidence exists concerning the contribution of electron-induced auto-ionization to the total ionization in the threshold region for these compounds. Therefore, we necessarily assume that single-direct ionization dominates the cross-section for electron-induced ionization of compounds of present interest. For this case, several theoretical analyses predict a value of one for the exponent w in the threshold law.[130–132] Ionization efficiencies obtained for polyatomic compounds and radicals using energy-resolved electron beams are consistent with a linear or an apparently linear threshold law, that is, if the threshold law is nonlinear, the region of nonlinearity falls within the energy resolution of the electron beam (0.07–0.08 eV).[133–139]

The assumption that the mass spectrum of a polyatomic molecule results from competing and consecutive unimolecular reactions of internally excited molecular ions led to the development of the quasi-equilibrium theory (QET).[140,141] Briefly, The RRKM (Rice–Ramsperger–Kassel–Marcus) rate constants, $k(E)$, for each unimolecular decomposition with a barrier height E_0 are calculated as a function of the internal energy E of the molecular ion. These rate constants and the reaction times are used to compute a breakdown graph that describes the yield of all ions in the reaction network quantitatively as a function of the internal energy of the molecular ion. Convolution of the breakdown graph with both the internal energy distribution function (P(E)) and the electron energy distribution function (EED) yields the mass spectrum. The P(E) corresponds to the convolution of the energy deposition function (P(ED)) and the Boltzmann function describing the thermal energy distribution of the neutrals prior to ionization. The P(ED) describes the probability of producing a molecular ion possessing an internal energy E as a function of the energy of the ionizing electron. Thus, P(ED) depends upon the Franck–Condon factors for electronic transitions from the various vibrational levels of the ground state of a molecule to the different vibrational levels of the various electronic states of the ion and upon the threshold law. The threshold law describes the probability of transferring an energy $E + IP_\kappa$ to the molecular ion as a function of the energy of the incident electron.

7.5 Practical Consequences of Fundamental Phenomena

Both the fundamental factors considered in the previous section and the operating characteristics of conventional electron sources have an impact on the practical application of low-voltage electrons as an ionizing medium. The threshold region for compounds of interest extends from about 6 eV to approximately 13 eV.[142] Equation (57) reveals that the cross-sections for ionization of these compounds by electrons having nominal energies in this range and energy distributions $m(V - IP_\kappa)$ depend upon the magnitudes of both the Franck-Condon factors for accessible transitions and the differences $V - IP_\kappa$. For a given value of the ionizing energy, the function $V - IP_\kappa$ will vary significantly in the threshold region as the ionization potential decreases. This conclusion is substantiated by the values in columns 3 and 4 of Table 13 for the compounds and ionization potentials listed in columns 1 and 2, respectively. Since the ionization potentials for aromatic hydrocarbons are lower than for saturated hydrocarbons, the threshold laws in column 5 are seen to be considerably larger for the former than for the latter. The values in columns 5 and 6 also show that the function $V - IP_\kappa$ increases with increasing aromaticity. A decrease in the electron energy by 3 eV is seen in column 7 to lead to a marked decrease in the magnitude of the threshold law for the three aromatic hydrocarbons.

The previous discussion reveals that the production of large numbers of molecular ions is facilitated by large values of $V - IP_\kappa$. However, the formation of molecular ions with insufficient energy to undergo decomposition at a given nominal value of the electron energy reflects the kinetics of fragmentation, the internal energy of the

Table 13 Effect of the threshold law on the electron impact cross-section for the ground electronic state

molecular ion and the EED. For a given value of V, the range of internal excitation energies available to the molecular ion is $0 \leq E \leq V - IP_1$. The RRKM rate constants, $k(E)_1$, increase rapidly as E rises above $E_{0,1}$, where $E_{0,1}$ is the barrier height for the lowest energy fragmentation reaction. Thus, production of high yields of stable molecular ions relative to fragment ions requires that only a relatively small fraction of the electrons in the beam have energies in excess of $IP_1 + E_{0,1}$.

The second derivative of the ionization efficiency (SDIE) for formation of an ionized atom in its ground electronic state reduces to the EED reversed with respect to energy provided that ion formation involves single direct ionization obeying a linear threshold law.[132] A SDIE for xenon obtained by numerical differentiation of an experimentally determined first derivative of the ionization efficiency (FDIE) of xenon in the threshold region is reproduced in Figure 11.[143] The FDIE curve

Figure 11 Second derivative of the xenon ionization efficiency curve in the threshold region. The EED is Maxwellian and reversed with respect to the energy axis. The FWHM of the first peak corresponding to the formation of $Xe^{\bullet+}$ in the $^2P_{3/2}$ state is 0.50 eV. The second maximum results from the 6d autoionizing state.

was obtained with a clean ion source and with the electron shield at zero potential with respect to the filament and with the extraction-plate potentials near the block potential to minimize the effect of contact potentials on the EED. The trap current was 20 μA to minimize space charge. The second maximum in the SDIE curve in Figure 11 which occurs at 12.8 ± 0.1 eV is caused by the 6d autoionizing state.[144] In agreement with theory,[132] the SDIE for formation of Xe^+ in the $^2P_{3/2}$ state is seen to correspond to a reversed Maxwellian distribution having a FWHM of 0.50 eV.

As seen in Figure 11, a significant probability exists that the ionizing beam will contain electrons having energies ranging from the nominal value up to about the nominal value plus 1.4 eV. Thus, molecular ions would be observed at nominal electron energies of approximately $IP - 1.4$ eV. Furthermore, the internal energies of the molecular ions can be increased over those present in the neutral precursor by amounts ranging from $V - IP$ up to $V - IP + 1.4$ eV. Thus, for $V = IP$ the EED shown in Figure 11 could produce molecular-ion decomposition reactions having $E_{0,1} \leq 1.4$ eV.

A number of experimental phenomena can increase the spread of electron energies in the ionizing region. For example, the use of 0.030 inch (0.0762 cm) rather than 0.020 inch (0.0508 cm) rhenium ribbon increased the FWHM of the EED from 0.42–0.55 eV to 0.63–0.74 eV.[143] An increase in the contamination of the ion source necessitates an increase (decrease) in the voltage applied to the repeller (extractor) electrodes which results in an increase in the FWHM of the EED. For example, SDIE curves for Xe having FWHM values in excess of 1 eV were obtained for contaminated ion sources. The FWHM of the EED is sensitive to the potential on the electron trap due to field penetration. For example, operation of a CEC 21-110B mass spectrometer at low-ionizing energies required modification of the ion source circuitry because penetration of the field resulting from the high fixed potential applied to the trap into the ionizing region sufficiently broadened the distribution of electron energies so that molecular ions

of benzene were observed at nominal electron energies below 1 eV.

Samples of interest generally require inlet and ion-source temperatures of 250 °C or greater. At these temperatures, the average thermal energy may attain considerable values for large molecules and the distribution of these energies will encompass a considerable range of energies because of the large number of degrees of freedom over which the thermal energy may be distributed. For, example, at 300 °C the average thermal energy of propane is ca. 0.3 eV and the FWHM of the Boltzmann distribution is approximately 0.3 eV.[145] At 327 °C the calculated thermal energy distribution for hexane has an average value of ca. 0.55 eV and extends from slightly greater than 0 eV up to ca. 1.5 eV.[146] The calculated average thermal energy of 2-phenyl-2-methylpropane at this temperature is about 0.8 eV and the calculated distribution ranges from about 0.2 to approximately 1.8 eV.[147] Since the thermal-energy content of the neutral species is fully effective in determining the kinetics of ion decompositions, the yield of fragment ions relative to molecular ions and the degree to which the ionization efficiency curves for these ions asymptotically approaches the energy axis increases with temperature for a given compound and with molecular size for a given temperature. For example, the thermal shifts of the ionization curves for a series of alkanes range from 0.10–0.24 eV as the temperature is raised from 28–142 °C.[148]

Appearance potentials for formation of fragment ions from saturated compounds are only a few tenths of a volt above their ionization potentials.[142] This fact together with the phenomena discussed above precludes the use of low-voltage electrons as the ionizing agent for performing homolog-type analysis of saturated hydrocarbons because of low molecular-ion signal magnitudes. Since the appearance potentials for fragment ions from aromatic compounds are generally greater then about 1–1.5 eV above their ionization potentials,[142] an electron energy can usually be selected that results in acceptably large molecular ion to fragment ion signal magnitude ratios.

7.6 Electron Impact Ionization and Photoionization Cross-sections

Total ionization cross-sections have been determined for a number of organic compounds.[129,149–157] Unfortunately, these cross-sections have only limited applicability with regard to predicting LVEI sensitivities for two reasons. First, except for benzene[129,149,150,153] and a series of its alkylated homologs[129,153] the cross-sections are for the ionization of compounds that are not of interest here. Second, the majority of cross-sections are for ionizations using 70–75 eV electrons. Harrison et al.[129] observed that the 75-eV cross-sections for ionization of benzene and its alkylated homologs increase with increasing carbon number up to a carbon number of nine. Within the limits of data precision, the cross-sections were found to be both carbon number- and isomer-independent for C_9 and C_{10} homologs. In contrast, Alberti et al. observed that the 75-eV cross-sections for benzene and *n*-alkylated homologs containing up to 15 carbons increased with increasing alkyl carbon number by a constant amount per CH_2 group.[153] Munson et al. also observed that the 70-eV cross-sections for -6(H) series homologs containing 2–10 alkyl carbons increased linearly with increasing carbon number but were, within the limits of data precision, isomer independent for a given homolog.[157]

The molecular-structure dependence of the total cross-sections for the ionization of organic compounds by electrons with energies in the region of 70 eV has been considered in terms of atomic and molecular properties. The suggestion[149] that molecular cross-sections correspond to the sum of the atomic cross-sections of the molecules constituent atoms has been shown[129,150,158] to be incorrect for the general case. The additivity approach has been modified to correlate total cross-sections for ionization of several classes of organic compounds by electrons having energies in the region of 70 eV.[129,152,154] EI cross-sections at 70–75 eV and 11.6–11.8 eV photoionization cross-sections[159] for a number of classes of organic compounds have been correlated with molecular properties such as the sum of the atomic cross-sections, polarizability, diamagnetic susceptibility and molecular volumes.[129,149,150,152,154–157,159] These linear correlations are not general but are different for each class of compounds.

It is not, a priori, obvious that low-voltage cross-sections can be reliably predicted from 70–75 eV cross-sections. In this regard, the relative cross-sections for ionization of 41 low-molecular weight alkanes, alkyl chlorides, ketones, aldehydes, ethers and alcohols by 11.6–11.8-eV photons were found[159] to be linearly correlated with those[129,152] for ionization by 70–75-eV electrons. LVEI efficiencies have been reported for a number of relevant aromatic compounds.[160] Since the ionization efficiencies were analyzed in terms of relative ionization probabilities rather then relative cross-sections, the results are considered in the next section.

7.7 Low-voltage Relative Mole Sensitivities for Ionization of Aromatic Compounds

Relative mole sensitivities for LVEI of aromatic hydrocarbons are tabulated in columns 6 through 11 in Table 14.[11,47,72,125–127] Relative gram sensitivities were converted to relative mole sensitivities values using the

molecular masses in column 5 which were calculated from the numbers of carbons and hydrogens in columns 2 and 3, respectively. Specific Z values are listed in column 4. Conditions used in determining these sensitivities are given in the footnotes to Table 14.

The footnotes in Table 14 reveal that the relative sensitivities were not determined using a uniform set of experimental conditions. The effects of differences in experimental conditions must be considered in any evaluation of the reproducibility of relative mole sensitivities. Dempster and Nier-Johnson geometry mass spectrometers were used in a number of the sensitivity determinations. Thus, the agreement might be considered to be quite good given that the mass range in the former instrument is scanned by varying the accelerating voltage rather then the magnetic field.

The inlet and ion-source temperatures used in determining the sensitivities in set 2 were probably at least 250 °C.[16,125] Ion-source temperatures for sets 1 and 5 were not reported; see footnotes a and e. Although the magnitude of the effect is dependent upon the structure of the neutral molecule, the sensitivities would reflect to some degree the use of different inlet-system/ion-source temperatures in these experiments. An increase in the contribution of hot-band transitions to the ionization efficiency caused by an increase in temperature would tend to increase the sensitivity except that sensitivities tend to decrease with increasing temperature due to increases in the thermal-energy content of the neutral which tends to increase molecular-ion fragmentations. For example, we have observed that the m/z 106 to m/z 91 signal magnitude ratio from *p*-xylene decreases as the inlet and ion-source temperatures are increased from 250–325 °C. The effect of different inlet and ion-source temperatures on the internal energies of the neutral prior to ionization and, hence, on sensitivities is unknown.

The footnotes in Table 14 reveal the use of different procedures for establishing the electron energies used in these sensitivity determinations. Crable et al.[11] used a nominal electron energy of 8 eV which was reported to correspond to an actual energy of 10 eV. This difference arises from contact potentials within the ion source. Thus, the actual ionizing energies used by Del Bianco et al.[72] and by Schiller[47] were undoubtedly greater then the reported nominal values of 9.2 and 10.0 eV, respectively.

Table 14 Experimental relative mole sensitivities for low-voltage ionization of aromatic hydrocarbons C_nH_x

Hydrocarbon	Values of			Formula weight	Experimental $S(m)_{rel}$ values from set					
	n	x	$-Z$		1[a]	2[b]	3[c]	4[d]	5[e]	6[f]

Spectra obtained using Kratos MS-30; repeller voltage maintained at the block potential; nominal electron energy = 10.0 eV; inlet = 325 °C; ion source temperature not specified.

[f] S.E. Scheppele, J.W. Miller.[127] Spectra obtained at 10 000–40 000 RP at 1000 s/decade; electron energy set to produce a *SM*(106) to *SM*(91) ratio of 20; inlet, transfer line, reentrance and ion source temperature were 300 °C.

[g] Isomer not specified.

[h] Average value.

The use of fixed values of the electron energy fails to take into account the effect of field penetrations and changes in the operating conditions of the ion source on the spread of energies in the electron beam in the region of ionization. In an attempt to minimize the effect of this phenomenon, Lumpkin and Aczel,[16,125] Scheppele and Sturm[126] and Scheppele and Miller[127] adjusted the electron energy to maintain a fixed *m*/*z* 106 to *m*/*z* 91 signal magnitude ratio from *p*-xylene. The use of signal magnitude ratios of 100 : 1,[125] 10 : 1[126] and 20 : 1[127] could account for some of the differences in sensitivities between sets 2, 3 and 6. It should be noted that we have routinely found that maintaining a fixed value of this ion abundance ratio requires decreases in the nominal value of the electron energy as the degree of source contamination increases for a given value of the ionizing (trap) current. This result is consistent with a broadening of the EED which in turn could result in variations in ion relative abundances and, hence, variations in relative sensitivities. The extent of acceptable ion-source contamination decreases with increasing trap current for increasing values of *SM*(106)/*SM*(91).

Deverse and King determined relative electron-impact ionization probabilities for the formation of stable molecular ions in the threshold region for a series of aromatic compounds.[160] The dependence of the relative mole sensitivities on the magnitude of the ionizing electron energy can be quantitatively estimated using these relative ionization probabilities. It is thus unfortunate that the work of Deverse and King appears to have been overlooked to date. Using a CEC 21-103C mass spectrometer, these authors determined the parent ion ionization-efficiency curves from near the ionization thresholds to about 12 eV. Equation (57) shows that the ion signal magnitude at each value of the electron energy is the sum of the ion signal magnitudes for formation

of various states of the molecular ion. The ''tails'' of the ionization efficiency curves were reported to be approximately 1.5 eV which from Figure 11 is consistent with a Maxwellian EED having a FWHM of at least 0.6 eV. At higher values of the electron energy, the ionization efficiency curves were observed to increase linearly with increasing ionization energy. The relative ionization probabilities were calculated on a mole basis from the linear portions of the molecular-ion ionization efficiency curves. The electron energy spread precluded detecting the formation of molecular ions in excited states. Consequently, the slopes effectively correspond to the sum of the ionization probabilities for formation of molecular ions in these states. Thus, from Equation (57) we obtain Equation (58) for calculating relative mole sensitivities

$$S(\text{mol})_{\text{rel}} = \frac{RTP_i(V - IP_i)}{RTP_{\text{ref}}(V - IP_{\text{ref}})} \tag{58}$$

where RTP_i and RTP_{ref} are the relative ionization probabilities for the ith and the reference hydrocarbons, respectively. Table 15 presents relative mole sensitivities in columns 7 through 11 calculated in 0.5-eV intervals from 9.5 through 11.5 for the hydrocarbons listed in column 1. These $S(\text{mol})_{\text{rel}}$ values were obtained using Equation (58) and the relative transition probabilities and ionization potentials in columns 5 and 6, respectively, of Table 15.

[c] Assumed values.

Comparison of the calculated relative mole sensitivities in Table 15 with the corresponding experimental values in Table 14 reveals that the different procedures employed in establishing the electron energies used in determining these latter values could account for a significant fraction of the apparent differences between a significant number of the experimental sensitivities. Inspection of Tables 14 and 15 reveals that the experimental $S(\text{mol})_{\text{rel}}$ values for hydrocarbons in set 1 having specific Z values less than or equal to -12(H), for benzene, chrysene and fluoranthene in set 4 and for pyrene in set 3 are exceptions that must reflect the occurrence of other phenomena.

The increase in senstivities with increasing molecular weight is seen in Table 14 to be generally largest in set 6. However, a potentially plausible explanation for at least a portion of this result is the use of a post-acceleration detector rather than an electron multiplier as used in the other studies given the fact that the gain of electron multipliers decreases with increasing ion m/z value.

The predicted $S(\text{mol})_{\text{rel}}$ values for pyrene and chrysene in Table 15 illustrate the effect of uncertainties in the ionization potentials on the magnitudes of the predicted sensitivities. As seen in column 6 of Table 15, the reported values for the ionization potentials of pyrene and chrysene range from 7.72 eV down to 7.31 eV and from 8.01 eV down to 7.72 eV, respectively. Columns 7 through 11 reveal that the lower ionization potential results in increased predicted $S(\text{mol})_{\text{rel}}$ values for pyrene with the increase decreasing from 23.0% at 9.5 eV to 10.9% at 11.5 eV. The corresponding increases for chrysene are 19.5% at 9.5 eV down to 8.3% at 11.5 eV.

The predicted sensitivities for indan and tetralin in Table 15 are seen to be significantly smaller than any of the experimental values in Table 14. Uncertainties in the ionization potentials can not account for these differences. The differences between the predicted and experimental sensitivities for these compounds is most likely to reflect phenomena such as errors in calculating the relative transition probabilities and/or greater degrees of molecular-ion fragmentation.

The *RTP* and *IP* values in Table 15 account for a number of anomalies that have been observed in attempts to correlate relative mole sensitivities for ionization of unalkylated aromatic hydrocarbons with quantities such as specific Z values and ionization potentials quantitatively for predictive purposes. For example, the *IP* for phenanthrene is about 0.25 eV greater than the *IP* for anthracene. The observation of similar relative mole sensitivities for these two hydrocarbons in Tables 14 and 15 reflects the fact that the larger *RTP* for phenanthrene essentially compensates for this difference in *IP*s. In Table 15, the predicted $S(\text{mol})_{\text{rel}}$ values for pyrene are seen to be larger or smaller than the predicted values for fluoranthene depending upon the *IP* assumed for the former compound. The experimental values in Table 14 indicate but do not prove that pyrene has the larger relative mole sensitivity. If additional experiments either confirm this indication or determine similar $S(\text{mol})_{\text{rel}}$ values for the two hydrocarbons then the result is another example of compensating differences in *RTP* and *IP* values unless the *RTP* values for either pyrene or fluoranthene or both are wrong. Although both biphenyl and acenaphthene are -14(H) series compounds, the experimental and predicted sensitivities for the latter are larger than those for the former. This result is consistent with the fact that the *RTP* and *IP* values for the acenaphthene are larger and smaller, respectively, than the corresponding values for biphenyl.

7.8 Summary

A number of conclusions and recommendations regarding the development of a universal database of low-voltage sensitivities are indicated by the contents of sections 7.1–7.7. The dependence of sensitivities for an agreed range of molecular structures should be ascertained and agreement should be reached regarding the acceptable range in inlet and ion source temperatures. A standard procedure for establishing the electron energy should be adopted. The simplest procedure is the attainment of a specified molecular ion to fragment ion relative abundance using a particular compound, for example, an m/z (106) to m/z (91) ratio of 25 : 1 from *p*-xylene. However, the differences in the electron energy distribution and the nominal value of the electron energy for attainment of a given relative abundance that can arise between mass spectrometers and for a given instrument as a function of the source and analyzer contamination will necessarily be reflected in the values for sensitivities to an extent presently unknown. Only rhenium filaments should be used.[8] The mass dependence of detector gain should be determined for each detector system and sensitivities should be corrected for any differences in these dependencies. It would be desirable to address the consequences of differences in the mass dependence of the analyzer transmission on sensitivities albeit to do so would undoubtedly be difficult. It should be determined to what extent sensitivities such as those in sets 1–6 in Table 14, excluding those discussed above, may reasonably approximate the repeatability and reproducibility that can be realized in the determination of a universal database of low-voltage sensitivities given the experimental variables that affect these values. Finally, publications should be required to specify the basis on which either absolute or relative sensitivities were determined, for example, mole, gram or volume, and the mathematical

operations performed in converting ion abundances to sensitivities.

MS	Mass Spectrometry
NMR	Nuclear Magnetic Resonance
P(E)	Internal Energy Distribution Function
P(ED)	Energy Deposition Function
PMD	Probe Microdistillation
QET	Quasi-equilibrium Theory
RHS	Right Hand Side
RIA	Relative Ion Abundance
RMS	Root Mean Square
RP	Resolving Power
RRKM	Rice–Ramsperger–Kassel–Marcus
SDIE	Second Derivative of the Ionization Efficiency
TDNOCI	Townsend Discharge Nitric Oxide Chemical Ionization

RELATED ARTICLES

Petroleum and Liquid Fossil Fuels Analysis **(Volume 8)**
Hydrocarbons Analysis: Introduction • Diesel Fuels Analysis • Lube Products. Molecular Characterization of Base Oils • Lubricant Base Oils: Analysis and Characterization of • Mass Spectrometry, Low-resolution Electron Impact, for the Rapid Analysis of Petroleum Matrices • Nuclear Magnetic Resonance Characterization of Petroleum • Petroleum Residues, Characterization of

Common industrial analytical procedures determine the overall physical or chemical characteristics of a petroleum product, which are necessary to market the product, but these methods provide little or no information concerning specific chemical components. This article focuses on standard methods which can be used to determine the composition of individual components or classes of components within various petroleum matrices. Gas chromatography (GC) coupled with low-resolution mass spectrometry (MS) is the most useful method for quickly identifying and precisely measuring specific components or classes of components in a petroleum matrix. Direct insertion probe mass spectrometry/mass spectrometry (DIP/MS/MS) can be used for less volatile and thermally labile petroleum components.

1 INTRODUCTION

Generally accepted industrial analytical procedures utilized for commercial petroleum products rarely determine any of the numerous actual chemical components in those products. Most industrial procedures only define the overall physical or chemical characteristics of a petroleum product that are necessary to market the product. Physical properties such as boiling range, density, viscosity, flash point, and vapor pressures are measured. Specific chemical characteristics such as carbon, hydrogen, and nitrogen content, total sulfur, average molecular weight, octane number, or cetane number are determined. This article will focus on the composition of individual components or specific classes of components in the common commercially available refined or natural petroleum products. Specific components or classes of components can be identified quickly and precisely quantitated using GC coupled with low-resolution MS, i.e. gas chromatography/mass spectrometry (GC/MS). DIP/MS/MS can sometimes be used for less volatile and thermally labile petroleum components. DIP/MS/MS is also a useful technique for determining the elemental sulfur content of crude oils. The selection of appropriate internal surrogates will greatly enhance identification, precision, and accuracy.

2 GENERAL COMPOSITION OF COMMERCIAL PETROLEUM PRODUCTS

Petroleum products are extremely complex. Crude oils contain thousands of hydrocarbon components, many of which have not been fully characterized. Some components are unique to only a few specific crude sources. A second complication is the large and varying range of concentrations of possible components. Individual component concentrations will range from parts per billion levels to percentage levels. This range will far exceed the dynamic limits of most analytical instruments. A third complication is that many components are extremely similar. Although hundreds of these components are structurally unique, still thousands of other components are isomeric. Many of these isomeric petroleum hydrocarbons have very similar chemical and physical properties.

It will be useful to describe the major types of components in common commercial liquid petroleum products. These products are listed below in ascending boiling ranges.

- *Aviation gasoline* contains primarily alkylate, which is a highly branched saturated hydrocarbon mixture ranging from hexanes to nonanes, plus tetraethyllead. It does not contain aromatics or olefinic (unsaturated) hydrocarbons. It has a nominal boiling range of 30–220 °C.
- *Motor gasoline* contains straight run gasoline, which includes all of the natural crude oil components in the gasoline boiling range. Additionally, gasoline contains special refinery streams such as alkylate, reformate (which is mainly toluene), ethylbenzene, xylenes, and C_3-benzenes, some benzene and naphthalenes, plus trace amounts of heavy polycyclic aromatic hydrocarbons (PAHs), olefinic alkylate, and sometimes substantial levels of methyl *tert*-butyl ether (MTBE) or other oxygenates. The nominal boiling range of gasoline is 30–220 °C.
- *Kerosene* has a very significant normal paraffin content ranging from nonane to nonadecane, usually with a maximum near tridecane or tetradecane. Kerosene also contains lower levels of aromatics and some naphthenics (cyclic aliphatics) in the corresponding boiling range. Kerosene does not contain olefinic hydrocarbons. Its nominal boiling range of major components is 140–240 °C.
- *Aviation jet fuel* has a composition and boiling range similar to those of kerosene.
- *Diesel fuel* also has significant normal paraffin content, which ranges from decane to tetracosane, and usually has a maximum near hexadecane. Diesel also contains some aromatics and naphthenics with corresponding paraffinic boiling range. Diesel usually contains ethylhexyl nitrate as a cetane enhancer. Diesel does not contain olefinic hydrocarbons. Its nominal boiling range is 220–340 °C.
- *Home heating fuel* has a composition and boiling range similar to diesel, but does not contain ethylhexyl nitrate.
- *Motor oils* primarily contain octadecane to C_{32} paraffinic, naphthenic, and aromatic hydrocarbons along with various lubricant additives. Motor oils do not contain olefinic hydrocarbons. Modern fresh motor oils do not contain nonalkylated PAHs. Many motor oils contain low levels of distinctive biomarkers. Motor oils may contain or be completely composed of synthetic esters or polyolefins. These synthetic motor oils can be easily differentiated from natural motor oils. The boiling point of motor oils starts around 330 °C and will extend beyond 400 °C.

  Within the above refined petroleum product classifications, the general chemical composition is fairly similar. However, the relative distributions of these chemical components are unique and can generally be useful for distinguishing one fuel from another in the same class.
- *Crude oils*, in contrast to refined products, vary greatly from each other. Still, a few generalities can be made. Crude oils usually contain a distinctive normal paraffin content over a wide boiling range. Crude oils do not contain olefinic hydrocarbons. They have relatively fewer branched-chain alkanes and more cycloparaffins in the gasoline range than motor gasoline. Crude oil will contain low levels of distinctive biomarkers, which are particularly useful fingerprints for identifying a particular crude oil. They generally contain low levels of nonalkylated PAHs. Crude oils may also contain elemental sulfur, S_8.

3 GENERAL METHODOLOGY

3.1 Reducing Petroleum Matrix Complexity

There are two significant physical properties of petroleum products that are generally used to simplify a liquid petroleum matrix: polarity and boiling point. Petroleum products can generally contain two broad polarity classifications, aliphatic and aromatic hydrocarbons. Aliphatic (including saturated, unsaturated and cyclic), hydrocarbons are relatively less polar than aromatic hydrocarbons. Simple chromatographic procedures, such as the use of solid-phase cartridges, usually can be used to separate

aliphatics rapidly from aromatics. Automated high-performance liquid chromatography (HPLC), if available, can also be very useful. Typically, crude oils, gasolines, diesel fuels, and many motor oils contain 15–30% aromatics. Boiling fractions will again simplify the petroleum matrix. Gasoline, kerosene, diesel fuel, and lubricants are, to a first approximation, boiling range fractions of crude oil. GC using nonpolar columns is a quick procedure to separate hydrocarbons by boiling point.

3.2 Gas Chromatography Combined with Low-resolution Electron Ionization Mass Spectrometry

Only GC/MS can resolve and identify petroleum products at the molecular level. The gas chromatograph has the separating power to resolve the thousands of compounds in petroleum products. The mass spectrometer will further separate even unresolved chromatographic peaks based upon their mass spectral characteristics. The mass spectrometer has a sufficient dynamic range and sensitivity to measure both the major and trace components. Most important, the mass spectrometer has the specificity to identify or at least characterize most of these complex hydrocarbons.

3.2.1 Instrumental Conditions for Gas Chromatography/Mass Spectrometry

Most product samples can be separated at least partially by medium-resolution GC using splitless injection on to a nonpolar capillary column (30 m × 0.25 mm ID or 20 m × 0.18 mm ID columns, 100% methylsilicone or 95% methyl–5% phenylsilicone phase). Complex samples require high-resolution GC conditions, using 100 m × 0.25 mm ID or 40 m × 0.10 mm ID capillary columns. The narrow-bore columns are preferable owing to the fast analysis time and low column bleed into the mass spectrometer detector, although some commercial gas chromatographs cannot handle the high head pressure required. The mobile phase velocity is set to 30 cm s^{-1} for helium carrier gas. A slow oven ramp is used to provide maximum chromatographic separation, up to the upper temperature limit of the column (usually 350–400 °C).

The mass spectrometer detector is configured with a direct capillary interface. It is operated in an electron ionization (EI) mode using an ionization energy between 50 and 100 eV. The mass range is set in full scan mode to 29–500 Da at unit resolution. The scan time is set to achieve at least eight scans per GC peak width at half-height. Quantitation is achieved using the most unique mass for each target component, usually the molecular ion, which is measured against the closest eluting internal standard of similar polarity. Isotopic internal surrogates will greatly enhance identification, precision, and accuracy.

3.3 Direct Insertion Probe Mass Spectrometry/Mass Spectrometry

When a petroleum component is not volatile and/or thermally labile, GC will be ineffective. However, DIP/MS/MS can often be an effective substitute for selected compounds. The first of the tandem mass spectrometers replaces the gas chromatograph. It is used to select a characteristic set of masses for a targeted compound, usually its molecular mass. The second mass analyzer is used to discriminate between those compounds with similar masses. An internal surrogate is still required for precision and accuracy. This technique is rapid and requires minimum sample preparation. The high selectivity can be tailored to the analyte even in the most complex of matrices, such as crude oils. DIP/MS/MS can be used to measure elemental sulfur, S_8, in crude oils. This is an excellent example of achieving selectively, high sensitivity, and accuracy with minimal analysis time.

3.3.1 Instrumental Conditions for Direct Insertion Probe Mass Spectrometry/Mass Spectrometry

The surrogate of the compound of interest is spiked at a known concentration into the petroleum sample. The spiked sample is then placed on a direct thermal probe and is slowly sublimed at low temperature directly into the source of the mass spectrometer. Although this slow evaporation or sublimation does provide some separation, the traditional total ion mass scan would still display only a continuous spectrum with hits at virtually every mass. However, when the tandem mass spectrometer is sequentially programmed to scan selective daughter ions that are key masses for the target compound and alternately for the surrogate compound, then quantitation can be achieved.

The mass spectrometry/mass spectrometry (MS/MS) conditions should be optimized for the target analyte. The selected ionization energy should maximize the target component's parent ion. Generally, the molecular ion is selected, but other distinctive ions may be used as the parent ion. The collision offset energy that provides the daughter ion fragments should also be optimized.

3.4 Specialized Internal Petroleum Surrogates

The surrogate compounds should have the same physical and chemical properties as the analyte and should not be naturally present in the petroleum matrix. Isotopically labeled aliphatics and aromatics make ideal surrogates. Isotopic surrogates over the entire petroleum hydrocarbon boiling range are generally available commercially. These surrogates are simple to use and easy to calibrate against target analytes. They both make identifications easier and greatly enhance accuracy of measurements.

Deuterated surrogates should be prepared and added just prior to analysis due to the possibility of isotopic exchange with solvents at high or low pH levels. Carbon-13 surrogates are stable, but are much more expensive. Examples of the various commercially available hydrocarbon surrogates and the corresponding petroleum product are as follows:

- Gasoline-range surrogates – percentage range concentrations of octane-d_{18}, benzene-d_6, toluene-d_8, ethylbenzene-d_{10}, styrene-d_8, butylbenzene-d_{12}, 4-ethyltoluene-d_3, and naphthalene-d_8; parts per million range deuterated PAHs.
- Kerosene- and diesel-range surrogates – parts per thousand range concentrations of hexadecane-d_{34}, methylnaphthalene-d_{10}, butylbenzene-d_{14}; parts per million range deuterated PAHs.
- Motor oil-range surrogates – parts per thousand range concentrations of octacosane-d_{58}, nonylpyrene-d_{28}, butylbenzene-d_{14}; parts per million range deuterated PAHs.
- Heavy crude oil-range hydrocarbons – same as motor oil. Use $^{34}S_8$ to determine elemental sulfur.
- Isotopic derivatives of common fuel additives such as deuterated MTBE, methyl-d_{12} *tert*-butyl ether.

4 APPLICATIONS

4.1 General Strategies for the Mass Spectrometry Analyses of Petroleum Components

Application examples of four general strategies for analyzing components in liquid petroleum matrices will be described. Very similar approaches can be applied for the analysis of just about any individual or group of semivolatile components found in any petroleum product. These general mass spectrometric strategies can be summarized as follows:

- The analysis of known, well-characterized and stable components that are present at moderate concentration levels (approximately 50 ppm or greater). The GC/MS analysis of the specific aromatics and oxygenates in gasoline will be used to illustrate this approach.
- The analysis of known, well-characterized and stable components that are present at low concentration levels (approximately 10 ppm or less). The HPLC cleanup and subsequent GC/MS analysis of the 2-aminonaphthalene in motor oil will be used to illustrate this approach.
- The analysis of less defined components that are present at moderate concentration levels (about 50 ppm or greater). Two approaches will be used as examples. First is the GC/MS analysis of specific alkylated PAHs in crude oil. The comparative analysis of trimethylphenanthrene and trimethyldibenzothiophene will be used to illustrate this approach. Second is the DIP/MS/MS analysis of the specific higher molecular weight alkylated PAHs in crude oil. The analysis of alkylbenzothiophenes and alkyldibenzothiophene in heavy oil fractions will be used to illustrate this approach.
- The analysis of known, well-characterized but thermally labile components that are present at moderate concentration levels (about 100 ppm or greater). The DIP/MS/MS analysis of elemental sulfur in crude oil will be used to illustrate this approach.

4.2 General Strategy for Well-characterized Components at Moderate Concentrations: Analysis of the Individual Aromatic Components in Gasoline

The GC/MS analysis of the specific aromatics and oxygenates in gasoline will be used as an example of the general strategy for the compositional analysis of known components at moderate concentrations. The gasoline matrix is the simplest of the liquid petroleum products, yet it still presents a challenge to analysis. Various GC methods have been used for many years to identify and quantitate gasoline components, but these methods have significant problems. Even when very high-resolution GC methods are used, co-eluting peaks and multiple isomers with different retention times complicate the resulting chromatograms. A stand-alone MS method, American Society for Testing and Materials (ASTM) Method D2789, which does not use a prior chromatographic separation, also has been used to determine the aromatic concentration in gasoline.[1] However, ASTM Method D2789 only provides general gasoline component classifications (i.e. paraffins, monocycloparaffins, dicycloparaffins, alkylbenzenes, indans plus tetralins, and naphthalenes). Furthermore, ASTM Method D2789 lacks precision because it assumes the probable distribution of aromatics in gasoline and requires that the gasoline be relatively free of olefins.

A combination of GC and MS overcomes the lack of analytical target specificity that is characteristic of the individual techniques when those techniques are used independently. GC/MS is an orthogonal hyphenated method that combines multiple complementary separation capacities of both methods. This combination results in an extremely powerful technique for the analysis of gasoline. The general strategy for applying GC/MS to the component analysis of aromatics in gasoline will now be described. A very similar approach can be applied

for the analysis of just about any individual or group of semivolatile components found in any petroleum product.

4.2.1 *Gas Chromatography/Mass Spectrometry of Aromatics in Gasoline Using American Society for Testing and Materials Method D5769*

The United States Environmental Protection Agency (USEPA), specified in the *Federal Register* in 1994 that GC/MS must be used to determine the total aromatics in gasoline.[2] The USEPA established performance guidelines, but only very general procedural guidelines. It permits the use of any GC/MS conditions and internal standards as long as the results are within a relative error of 2.0%. This progressive legislation allowed the petroleum and environment laboratories to develop their own particular methodologies. The Texaco Upstream Technology laboratory worked closely in a joint effort with other laboratories to develop specific details to optimize the performance and minimize the complexity of this new USEPA method. The result of this effort was ASTM Method D5769.[3]

The GC/MS conditions for ASTM Method D5769 are summarized at follows. The gas chromatograph is equipped with a 100% polymethylsiloxane open-tubular GC capillary column. The method suggests using a 60 m × 0.32 mm ID column which is operated at 50 °C (1 min), ramped at 2 °C min^{-1} to 190 °C. The total acquisition time will be 71 min. The mass spectrometer is operated under 70 eV EI conditions. The method required a minimum full-scan sampling rate of five scans across peak widths at half-height.

The ASTM Method D5769 internal standards are perdeuterobenzene, perdeuteroethylbenzene and perdeuteronaphthalene. Perdeuterotoluene is optional. (The hydrogen atoms in a perdeutero compound have been totally substituted for deuterium atoms.) The resulting compound is an internal surrogate with almost the same GC retention time as the corresponding aromatic component. The deuterated surrogates will actually have a slightly lower GC retention time. Of course, the mass spectrum of the deuterated surrogate will be completely different, since deuterium has an atomic mass of 2 Da. However, the deuterated surrogate will have an analogous mass spectrum corresponding to the natural component spectrum. The relative GC/MS response factors for individual pure components (from benzene through all of the major aromatics up to C_{11}) are measured relative to the response of the deuterated standards. A typical calibration, in this case for benzene, is shown in Figure 1. The coordinates are relative response vs relative amount. The slope of the line is the response factor. In our laboratory each of five concentrations across the calibration range was measured at least three times prior to calculating response factors. The fit is essentially linear with a coefficient of correlation of 0.9999. All major aromatic compounds are calibrated separately, generally using molecular ions in the mass spectrum for quantitation for most species.

Figure 1 Calibration curve for benzene. The slope is a straight line, which is indicative of a linear response factor.

The deuterated internal standard mix is weighed into a 10-g sample of gasoline to the nearest 100 µg. A 12-component quality control (QC) mix is prepared by weight. The QC sample is then run. ASTM Method D5769 specifies that each individual aromatic species in the QC mix must be measured within 5% relative of the true, weighed concentration. Any additional unspecified experimental conditions used are acceptable, as long as this specification is obtained. The weight percentage of each target aromatic component is then calculated. (The volume percentage of that component is calculated from the density of the pure component relative to the sample density.) A synthetic gasoline consisting of known weighed amounts of pure gasoline components is then run as a QC sample. The measured total aromatics for this QC standard must be within 2.0 wt% of the weighed total aromatics. The ASTM Method D5769 statistical specifications are significantly tighter than those specified by the USEPA, since the USEPA requires that only the total aromatics of the QC mix be within 2% accuracy.

4.2.2 *Gas Chromatography/Mass Spectrometry of Aromatics in Gasoline Using a Very Fast and More Precise Version of American Society for Testing and Materials Method D5769*

This laboratory developed a very rapid and more precise modification for ASTM Method D5769.[4] The analysis

Figure 2 A selected ion chromatogram of *m/z* 120. The narrow-bore column elutes all of the C_3-benzenes within 30 s.

Figure 3 Calibration curve for toluene. The slope is linear, when calibrated against deuterated toluene, using *m/z* 99 and 100.

time was greatly reduced by applying fast GC column technology. Our laboratory specifies using either a 20 m × 0.10 mm ID or 20 m × 0.18 mm ID 100% polymethylsiloxane open-tubular column with a 25 °C min^{-1} ramp rate. These GC conditions reduce the total acquisition time to only 9 min vs 71 min and the chromatography is still well within the chromatographic resolutions specified in ASTM Method D5769. These narrow-bore columns are available from numerous manufacturers. Figure 2 shows a selected ion chromatogram in the range of C_9 alkylbenzenes (trimethylbenzenes, ethylmethylbenzenes, and propylbenzenes). The C_9 benzenes eluted totally within 6 min and with a GC resolution which meets or exceeds that published in ASTM Method D5769 for a 90-min version using the more traditional wider bore and longer columns. The peak widths are approximately 0.5 s. For such a peak width, ASTM Method D5769 requires a full-scan MS sampling rate of 10 scans s^{-1} (five scans across the peak at half-height). The MS sampling rate was actually 13 scans s^{-1} in this case. Most commercial mass spectrometers can easily scan at these rates.

4.2.3 Other American Society for Testing and Materials Method D5769 Modifications

The modified method improves the precision of ASTM Method D5769 while staying within its method parameters. The additional precision was achieved through the following three modifications. First, the addition of perdeuterotoluene to the internal standard mix increases the precision of toluene determination significantly. Perdeuterotoluene is optional for the standard version and has the least precision of any component in the standard ASTM Method D5769. The modified internal standard mix is added at approximately 10% by weight to each sample to give approximately 1 wt% benzene-d_6, 7 wt% toluene-d_8, 1 wt% ethylbenzene-d_{10}, and 1 wt% naphthalene-d_8. The result significantly increases the precision, since toluene generally has one of the highest concentrations of any individual component in gasoline. When toluene is quantitated against perdeuterobenzene, generally a quadratic calibration fit is required. However, when perdeuterotoluene is added at 7% in the sample, the linear range of the calibration curve is extended by almost one order of magnitude. Figure 3 shows linear calibration curves for toluene with an excellent correlation coefficient.

Second, the effective instrumental operational dynamic range of the mass spectrometer is significantly enhanced using microbore GC columns. The sensitivity specification in ASTM Method D5769 requires a detection limit of diethylbenzene at 20 ppm and a calibration curve for toluene that extends to 20%. Significant care must be taken in tuning the mass spectrometer to achieve such a wide dynamic range, but the selection of the proper GC conditions can extend the dynamic range of the GC/MS instrument far beyond the range of the MS detector alone. By using narrow-bore GC columns (0.1–0.18 mm ID) with a fast GC temperature ramp, it is possible to sharpen the small peaks while broadening the large peaks (column saturation), thus limiting the amount of material passing into the ion source at any given time. Although major components, such as toluene, may be saturated in the GC column, the MS detector is not saturated. The precision of the analysis is not affected and even the chromatographic resolution is still acceptable.

Third, the internal standard calculation requirements of ASTM D5769-95 can be another source of error. The method suggests using molecular ions for calibration,

Table 1 Six repetitive results for a gasoline analyzed using the modified version of ASTM Method D5769. Weight/weight percentages

but many deuterated standards are only commercially available at less than 100% nominal isotopic purity. For example, perdeuteroethylbenzene is available in nominal 98% isotopic purity. Therefore, a problem may occur when this imperfect internal standard is use. The molecular ion (unfragmented ion) will be distributed between *m*/*z* 116 (C_8D_{10}) and *m*/*z* 115 ($C_8D_9H_1$). Since *m*/*z* 116 cannot lose hydrogen, *m*/*z* 115 cannot be a fragment of *m*/*z* 116. A batch of perdeuteroethylbenzene internal standard deuterated to 98.1% has an *m*/*z* 115/116 ratio of 20%, whereas another batch deuterated to 99% has an *m*/*z* 115/116 ratio of 10%. Using just the *m*/*z* 116 ion to quantitate this internal standard, as the method suggests, could cause significant error since the internal standard added to samples could be from a different batch than that used for calibration. In our laboratory, the sum of the intensities observed for both the molecular ions of the zero hydrogen and one hydrogen analogs of each internal standard were used to maximize precision and accuracy. For example, *m*/*z* 99 and 100 were used for toluene-d_8, as seen in Figure 3.

Table 1 shows for a typical sample the precision that can be obtained when incorporating these three easy to implement modifications. Total aromatics of the six repetitive analyses range within 0.48% of each other and within a comfortable 0.30% of the mean. The EPA requires that the calibration mixture, which is less complex to analyze than actual gasoline, to agree within 2.0% of the actual measured preparation value.

4.2.4 American Society for Testing and Materials Method D5769 Bias

ASTM Method D5769 contains some bias. The USEPA mandate does not include the higher aromatics such as C_{10+} alkylnaphthalenes, C_{12+} alkylbenzenes, styrenes, and alkylindenes, which are found in gasoline, but at relatively low concentrations. ASTM Method D5769 tries to correct this problem by selecting pentamethylbenzene to establish the response factors for the uncalibrated heavier alkylbenzenes. Unfortunately, out of the hundreds of C_{11} and C_{12} alkylbenzenes, only pentamethylbenzene and hexamethylbenzene do not contain benzylic carbon–carbon bonds. Alkylbenzenes with a weak benzylic C–C bond have molecular ions that are approximately 30% smaller than those for alkylbenzenes without a benzylic C–C bond. Therefore, estimating these uncalibrated components against the pentamethylbenzene calibration curve will produce results which are 30% lower than the actual value. In our laboratory, uncalibrated components are quantitated using response factors calculated from the aggregate response of the calibrated compounds butylbenzene, 1,4-diethylbenzene, and 1,2-diethylbenzene. These components are reported as 'long chain C_4-benzenes'. When a long-chain alkylbenzene is

used to estimate for uncalibrated compound response, the bias will disappear.

4.2.5 Expanding the Scope of American Society for Testing and Materials Method D5769

Again the method for total aromatics in gasoline can serve as a template for the analysis of any component in gasoline. Additional gasoline components can be added to the list of eluting targets with essentially no additional analysis time or loss in quantitative quality. For example, this laboratory easily modified ASTM Method D5769 to include MTBE and TAME. MTBE and TAME are common oxygenate additives that can be found in gasolines, especially during winter months. The fragment ion at *m*/*z* 73 was used to measure the two ethers, since the molecular ions of these nonaromatic species are weak or absent in their EI spectra. ASTM Method D5599 is a GC method with oxygen flame ionization detection (OFID) that is recommended for measuring gasoline oxygenates. Both methods produce essentially the same answer, but the modified ASTM Method D5769 also simultaneously provides gasoline aromatic content. Figure 4 is a plot of the results for both methods at low and high concentration levels of MTBE and TAME. The response curve is linear throughout the range.

4.3 General Strategy for Well-characterized Components at Low Concentrations: Analysis of the Trace Components in Refined Oils and Crude Oils by Gas Chromatography/Mass Spectrometry and Liquid Chromatography

The analysis of trace-level components in motor oil or heavy crude oils is one of the most challenging petroleum analyses. Heavy hydrocarbon mixtures are more difficult to analyze because the individual components have higher molecular weights. Large molecules contain more possible combinations of atoms. There is a continuous array of molecules with similar boiling points and molecular weights throughout even narrow boiling distributions. When GC/MS alone is applied for the analysis of trace components in a heavy petroleum matrix, the analyte ions can be lost in a continuum of interfering background noise. In these cases, solid-phase chromatography or HPLC can often be used to reduce the complexity of the matrix. The analysis for 2-aminonaphthalene in motor oil using HPLC cleanup prior to GC/MS will be used as example.

Figure 4 ASTM Method D5769, when modified to include oxygenates, produces the same results as ASTM Method D5599. MTBE and *tert*-amyl methyl ether (TAME) (*m*/*z* 73) calibrated against benzene-d_6 (*m*/*z* 84).

4.3.1 Analysis for 2-Aminonaphthalene in Motor Oil Using High-performance Liquid Chromatography Clean-up Prior to Gas Chromatography/Mass Spectrometry

2-Aminonaphthalene has long been recognized as a human carcinogen. It is crucial to establish that it is not present even at trace levels in petroleum products which may come into contact with potable water or food packaging equipment. The motor oil is spiked at the low parts per million levels with a deuterated surrogate of 2-aminonaphthalene and analyzed by a general strategy similar to the general methodology used for determining the aromatic content of gasoline. The gas chromatograph was operated with column

Figure 5 Selected ion traces at (a) *m*/*z* 143 and (b) *m*/*z* 150 for an oil sample spiked at 5 ppm with 1-aminonaphthalene and 2-aminonaphthalene-d_7 prior to HPLC cleanup. The chromatogram fails to indicate their presence above the background noise.

temperature programming from 70 °C at 8 °C min^{-1} to 320 °C. A 1-μL volume of sample was injected on to a 30 m × 0.25 mm ID, 0.25-μm phase thickness, fused-silica capillary 5% phenyl–methylsilica column with a flow rate of 40 cm s^{-1}. The mass spectrometer was operated at nominal mass using EI with an ionization energy of 70 eV. The instrument was scanned over a mass range from 50 to 250 Da every 0.75 s. The analysis failed. There are too many interfering components in the same retention time window and with the same fragment ions. Figure 5(a) and (b) shows GC/MS selected ion chromatograms of motor oil spiked at the 5 ppm level with both 1-aminonaphthalene and 2-aminonaphthalene-d_7. Both compounds will elute between 20 and 21 min under these GC conditions. The molecular ion trace for aminonaphthalenes, m/z 143, is questionable. The molecular ion trace for the deuterated surrogate, m/z 150, shows only noise. Even though the results are ambiguous, they are superior to others. One State and two commercial environmental laboratories actually falsely reported 2-aminonaphthalene present in this oil.

This laboratory developed an HPLC procedure that will quickly and unambiguously determine if 2-aminonaphthalene is not present in refined oils or crude oils at trace levels.[5] First, 25 μL of the original spiked oil was injected on to a 250 × 4.6 mm ID cyano column and eluted with a 5% solution of methylene chloride in hexane, then the fraction containing the aminonaphthalenes was collected and evaporated to about 25 μL.

Figure 6 Selected ion traces at (a) m/z 143 and (b) m/z 150 for an oil sample spiked at 5 ppm with 1-aminonaphthalene and 2-aminonaphthalene-d_7 after HPLC cleanup. The chromatogram clearly indicates their presence of both compounds.

Finally, the GC/MS procedure was repeated under the previous conditions. Figure 6(a) and (b) shows selected ion chromatograms of the cleaned-up oil. The deuterated 2-aminonaphthalene surrogate and 1-aminonaphthalene are clearly present at the 5 ppm level. There is no evidence of the natural 2-aminonaphthalene, since that compound would have eluted just after its deuterated surrogate when using these GC conditions. The retention time for the natural (non-deuterated) 2-aminonaphthalene was verified in subsequent analyses.

This procedure has a lower limit of detection of approximately 500 ppb. Still lower detection limits would have been achieved with selected ion detection. However, the mass spectrometer was operated using a full mass range in this case to assure that the HPLC cleanup procedure completely eliminated hydrocarbon interferences from the oil. This procedure was then supplied to the commercial environmental laboratories that initially used straight GC/MS without HPLC cleanup and had initially reported 2-aminonaphthalene to be present in this oil at the low parts per million level. The commercial laboratory then also verified that 2-aminonaphthalene was absent.

Special precautions must be taken when using a deuterated surrogate, since deuterium can exchange with some solvents and matrices, especially under acidic or basic conditions. In one case, one of the labeled aromatic ring positions adjacent to the amino group exchanged with the solvent, methylene chloride, during prolonged storage. A 6-week-old methylene chloride solution showed over 80% 2-aminonaphthalene-d_6 and only 3% of the original 2-aminonaphthalene-d_7. Standards should be prepared shortly before use and stored, if necessary, cold.

4.4 General Strategy for the Analysis of Less Defined Components Present at Moderate Concentrations

The most challenging target analyte is a target that is poorly characterized. Many petroleum components have not yet been isolated and therefore their actual physical properties are unknown. Furthermore, many components may never be isolated because of the complexity of the petroleum matrix and the expense of thorough analyses. In these cases, it is more practical to analyze classes of hydrocarbons, which can be loosely defined by their basic chemical properties and carbon framework. Members of individual class types will consist of isomers and homologs, varying from each other only by position and type of aliphatic groups attached to the particular carbon framework. These carbon frameworks can be generalized as various combinations of aliphatics, olefinics, naphthenics, aromatics, and naphthoaromatics. Traditional methods were developed in the 1950s using batch-inlet electron ionization mass spectrometry (EIMS). These hydrocarbon type analyses are still useful in some cases for

Figure 7 Total ion chromatogram of a diesel fuel with selected ion traces at *m*/*z* 220 and 226, eluting in the 20–22 min time interval.

characterizing middle distillates and vacuum gas oils.[6–8] However, GC/MS and DIP/MS/MS now permit these traditional analyses to be customized more selectively within individual hydrocarbon types. The information is especially useful for predicting general physical and chemical properties of petroleum products.

4.4.1 Gas Chromatography/Mass Spectrometry Analysis of Alkylated Polycyclic Aromatic Hydrocarbons in Petroleum Products

GC/MS response factors for alkylated polyaromatic hydrocarbons are either difficult to generate or unavailable. However, the GC data are internally consistent over short boiling ranges, when comparing within one or within two similar homologous series. For instance, the relative amounts of two different alkylated PAH homologs, which are both alkylated to the same extent, are commonly used to differentiate middle distillate products or crude oils from each other.[9] For example, Figure 7 shows the total ion chromatogram of a diesel fuel and two selective ion traces extracted from it. The selective traces show only trimethylphenanthrenes (*m*/*z* 220) and trimethyldibenzothiophenes (*m*/*z* 226), which eluted in the 20–22 min time interval. The total peak areas of trimethyldibenzothiophenes are then divided by the corresponding sum of the trimethylphenanthrenes. This ratio is called the D3/P3 index and is characteristic of the particular sample. For example, the D3/P3 index of a low-sulfur diesel fuel will range typically from 0.10 to 0.30. An Arabian Light Crude Oil may have an index as high as 4.06. The general pattern within a particular alkyl-PAH sequence is also

Figure 8 Total-ion, low-voltage EI mass spectrum of a heavy petroleum fraction.

valuable for determining the source or fingerprints for a petroleum product.

4.4.2 Direct Insertion Probe Mass Spectrometry/Mass Spectrometry Analysis of the Specific Alkylated Polycyclic Aromatic Hydrocarbons in Crude Oil

The heavier components of crude cannot be analyzed by GC/MS since they cannot be effectively resolved by GC or are simply not volatile. However, DIP/MS/MS is useful for analyzing specific higher molecular weight alkylated PAHs in crude oil. The general procedure follows: the high-boiling crude oil cut is placed in a quartz direct insertion probe tube and inserted into the source of a mass spectrometer. The sample is heated from 50 to 450 °C at 50 °C min^{-1} and held for 5 min. The mass spectrometer is operated under EI conditions using an ionization energy of 20 eV. The resulting total ion mass, presented in Figure 8, is of low value. It does clearly show a bimodal ion distribution. The lower mass distribution represents fragmentation ions and the higher mass distribution represents a continuum of molecular ions. However, this molecular ion distribution can be nearly resolved using parent mode MS/MS. The parent ions of *m*/*z* 197, 213, 215, 217, 221, 219, 223, and 225 were sequentially scanned. Figure 9 reveals a distribution of dibenzothiophenes that are generated by the parent ions of *m*/*z* 197. Figure 10 reveals a distribution of benzothiophenes that are generated by the parent ions of *m*/*z* 217.

4.5 General Strategy for Well-characterized but Thermally Labile Components at Moderate Concentrations: Direct Insertion Probe Mass Spectrometry/Mass Spectrometry for the Determination of Elemental Sulfur in Crude Oil

Elemental sulfur in crude oil can range from trace amounts to low percentage levels in mixtures, which are sometimes nonhomogeneous. The traditional analyses for measuring sulfur in crude oil have been limited to wet chemical methods. These techniques are time-consuming, are cumbersome, require skilled technicians, and still generally lack accuracy and precision. These analyses are further complicated because of the physical and chemical properties of elemental sulfur (sulfur has a low sublimation temperature, low and differing solubilities in the various crude oils, moderate reactivity with air, and even a modest thermal reactivity with hydrocarbons in the crude oil matrix).

DIP/MS/MS, when used in conjunction with an isotopicaly labeled sulfur-34 surrogate, provides a rapid and accurate method for determination of natural sulfur in crude oils.[10] Elemental sulfur-34 is spiked directly into the crude oil at 0.1 wt% and allowed to dissolve thoroughly overnight. The homogeneous spiked sample is then placed on a direct insertion probe and introduced into the mass spectrometer while being held at 30 °C. The sulfur is non-reactive at this low temperature, but will still sublime easily in the low-pressure environment of the mass spectrometer's ion source. Since the probe was never heated, most of the crude remains on the probe.

Figure 9 Mass spectrum showing parent ions of *m*/*z* 197.

Figure 10 Mass spectrum showing parent ions of *m*/*z* 217.

Figure 11 Normal total-ion EI mass spectrum of a direct insertion probe crude oil sample. Sulfur peaks are not prominent.

The mass spectrometer was sequentially programmed for one full-range scan and four daughter mode scans under EI conditions at 70 eV ionization energy. The full-range scan was from 250 to 285 Da. The daughter ions of *m*/*z* 256, 258, 270, and 272 were collected starting at mass 75 to the mass of the daughter ion minus 2 Da. The collision offset was set at 10 eV. Scan time was 1 s for each scan. Figure 11 shows the full-range mass scan. The key molecular ions for elemental sulfur at 256 Da and the surrogate at 272 Da are completely obscured by a continuum of interfering hydrocarbon ions. No successful quantitation could be obtained from the straight full-scan mass spectrum. Figure 12(a) and (b) presents the daughter ion scans of *m*/*z* 256 and 272. The parent ion of *m*/*z* 256 ($^{32}S_8$) produces a strong daughter ion at *m*/*z* 160 ($^{32}S_5$), representing the loss of three atoms of sulfur-32. The parent ion of *m*/*z* 272 ($^{34}S_8$) produces a strong daughter ion at *m*/*z* 170 ($^{34}S_5$), representing the loss of three atoms of sulfur-34. The experimentally measured data for the daughter ions of *m*/*z* 160 and 170 are then normalized for the initial relative abundances of the parent ions of *m*/*z* 256 and 272 in the pure molecular clusters of the natural sulfur and the enriched sulfur. For example, the abundance of $^{32}S_8$ in natural elemental sulfur is 66.5%. Dividing by 0.665 normalizes the experimental measurements. The molecular isotopic abundances for the natural sulfur and the surrogate abundance were easily determined from the mass spectra of the pure components. Figure 13(a) and (b) shows the molecular ion distribution and relative contributions for the parent ions. Equation (1) can be used to calculate weight percentage of sulfur in the oil:

$$\text{sulfur (wt\%)} = {}^{34}\text{S (wt\%)} \frac{\text{normalized response of natural sulfur}}{\text{normalized response of } {}^{34}\text{S}} \quad (1)$$

Two precautions should be considered. First, when working with isotopic internal standards, general response factors will take into account variations of the nominal values in isotopic distributions stated by the supplier. However, when a new batch of standards is

Figure 12 Daughter ion EI mass spectra of a direct insertion probe crude oil sample. S_5 fragment ions are dominant.

Figure 13 Molecular ion distributions for (a) elemental sulfur (S_8) natural and (b) isotopic sulfur ($^{34}S_8$).

used, new response factors must be generated. Second, elemental sulfur is hygroscopic and the extent of hydrate formation must be determined in the surrogate so that the true amount of spike will be known.

5 CONCLUSION

Specific hydrocarbon components or classes of components can be quickly identified and precisely quantitated using GC coupled with low-resolution MS. DIP/MS/MS can sometimes be used for less volatile and thermally labile petroleum components. The selection of appropriate internal surrogates will greatly enhance identification, precision, and accuracy. The application of four general strategies for analyzing components in liquid petroleum matrices serves as templates only. Very similar approaches can be applied for the analysis of just about any individual or group of semivolatile components found in any petroleum product.

When petroleum (i.e. crude oil) is distilled, a residual fraction containing molecules that do not volatilize is drawn off the bottom. This "resid" has an increased concentration of minor impurities, including sulfur-, nitrogen-, and oxygen-bearing heterocyclics, soluble nickel and vanadium compounds and a variety of trace metals. These impurities both dominate the unique properties of the resid and play a major role in determining the refining processes necessary for its conversion to marketable products. This article introduces the common analytical techniques for the measurement of sulfur, nitrogen, nickel, vanadium, and trace metals in this challenging organic matrix.

1 INTRODUCTION

Crude oils exhibit a broad range of elemental composition because they are formed by a combination of deposition, degradation, and transformation of ancient organics from different biosources.[1,2] In addition to hydrocarbons, crude oil contains a multitude of minor impurities, including sulfur-, nitrogen-, and oxygen-bearing heterocyclics, soluble nickel and vanadium compounds and a variety of trace metals that are removed in refining. When crude oil is distilled, a residual fraction containing molecules that do not volatilize is drawn off the bottom. This "resid" has an increased concentration of the heterocyclics and practically all of the metals. However, resid is valuable because it compares favorably with alternate hydrocarbon resources (bitumen, heavy oil, shale oil, and coal liquids) in terms of these deleterious contaminants and it is accessible in the refinery.[3,4] This article introduces the common techniques available for analysis of sulfur, nitrogen, nickel, vanadium, and trace metals in this challenging organic matrix.

2 PETROLEUM RESIDS

2.1 Origin

Commercially, resids are produced in the distillation unit that is the initial refinery treatment of a crude oil. In this unit, the oil continuously flows in sequence through a desalter, heat exchangers, an atmospheric pipestill (APS) and a vacuum pipestill (VPS). The bottoms from the APS (650 °F$^+$ (343 °C) or atmospheric resid) are reheated and distilled under vacuum (15–100 Torr) in the VPS. The application of vacuum allows the VPS to produce distillation bottoms (vacuum resid) with an atmospheric equivalent boiling point (AEBP) of 1050 °F$^+$ (566 °C).[3,4] In this scheme, both distillation units keep the actual temperature below 650 °F$^+$ (343 °C) to minimize cracking of the oil.

In addition to the continuous distillation in a refinery, laboratories use batch distillation methods to produce experimental "resids" with different AEBP. Distillation to a 650 °F$^+$ resid is done in accordance with ASTM (American Society for Testing and Materials) D 2892.[5] In this 15/5 distillation under reflux, the distillation temperature is gradually increased and a series of distillate fractions removed; the pressure is then reduced to ~10 Torr to reach the AEBP of 650 °F$^+$ without cracking

Encyclopedia of Analytical Chemistry

the oil. The 650 °F$^+$ bottoms is then charged into a second still where fractions are distilled in accordance with ASTM D 5236 down to pressures down to 0.1 Torr and AEBP of 1050 °F$^+$. Deeper distillations (1050–1300 °F$^+$, AEBP) are carried out at high vacuum with thin film evaporators with short vapor pathlengths.[6,7] Each short-path distillation produces a distillate and a bottoms; so multiple distillations are employed to generate the bottoms from 1050 to 1300 °F$^+$.

2.2 Range of Composition

With the exception of trace metals, the typical elemental composition of crude oil and of the corresponding resids varies only slightly over narrow limits (Table 1).[6] However, the percentage of resid and percentage of sulfur in the resid differ widely among crudes (Table 2).[8] Sulfur and nitrogen concentrations increase with the final boiling point of the resid fraction (Table 3).[7] Although the numbers are not included in the tables, practically all the metals remain in the resid as well. Data for DISTAC distillation of the atmospheric residue from a heavy California crude (Kern River) show that the 1000 °F$^+$ resid is nearly half the 775 °F$^+$ resid and twice the 1300 °F$^+$ resid (Table 4).

Extensive studies have been carried out to characterize the deep vacuum distillates.[7] The resids produced in these studies show steady increases for S, N, and O from 775 to 1300 °F$^+$, with the exception of metals. While no metals are volatilized below 1050 °F$^+$, some metals do, however, distill into cuts between 1050 and 1300 °F$^+$. The results for the heterocyclics in the deep distillates demonstrate that the molecular types found in the lower boiling fractions are found in the resids, as well. Resid can be considered to fit a ball and string model where the balls are fused aromatic (or naphthenoaromatic) rings and the strings are carbon or heteroatom links between the rings. While the number of fused rings in the resid may be larger than in vacuum distillates or may contain metals absent from those fractions, most of the molecular types retain their characteristic reactivity. Therefore, many of the analyses determining the elemental and molecular-type composition of resid are a logical extension of those used for the vacuum distillates.

Table 1 Range of elemental composition for whole crude and residues

Element	Whole crude (range)	Atmospheric resid (range)	Vacuum resid (range)
Carbon (%)	83–87	86–88	83–86
Hydrogen (%)	10–14	10–13	9–13
Sulfur (%)	0.04–6.0	0.05–7	0.1–12
Nitrogen (%)	0.02–1.0	0.05–1.2	0.1–1.5
Oxygen (%)	0.05–1.5	0.2–2.5	0.5–3
Nickel (wppm)	0.1–100	0.5–200	1–300
Vanadium (wppm)	0.1–500	0.2–800	0.5–1000

2.3 Physical Properties

The physical properties of resids make them a challenge for analysis (Table 5). Nothing can be seen or measured optically in resids because they are so dark. Resids may be lighter or heavier than water (API gravity = 10).

Table 2 Atmospheric and vacuum residue distributions for various crudes[8]

Crude	Region	% S in whole crude	Atmospheric resid			Vacuum resid		
			Wt%	% S	% S in 650+	Wt%	% S	% S in 1050+
Tapis	Malaysia	0.023	17.6	0.070	53.6

1300	25.7

Table 5 Physical properties of atmospheric and vacuum resids[a]

Property	Atmospheric resid	Vacuum resid
Boiling range (°F)	650+	1050+
API gravity	10–35	−5–25
Viscosity (cSt, 210 °C)	6–100	350–55 000
Carbon residue (%)	1–14	5–35
Pour point (F)	20–140	75–200
Asphaltenes	1–15	2–30

[a] Physical property ranges summarized from data in Speight,[6] Altgekt and Boduszynski,[7] and Kinney.[8]
API, American Petroleum Institute.

Measurements by ASTM tests show that resids vary in solubility (asphaltenes), viscosity, and tendency to form coke (carbon residue), all factors that complicate sample preparation.

3 DETERMINATION OF SULFUR IN PETROLEUM RESIDS

There are several standard methods suitable for measuring sulfur in resids. Sulfur can be measured directly in the resid matrix with X-ray fluorescence (XRF) or indirectly by titration or infrared detection (IR) after combustion to SO_2. Standard analytical practice includes a number of variations on these two approaches. Other S-sensitive methods are not as well suited for resid.

3.1 X-ray Fluorescence

For XRF analysis, a sample is placed in a disposable cell with a thin Mylar® or polypropylene window, the cell placed (window down) over a fluorescence detector, and the contents of the cell irradiated at fixed angle by an X-ray tube with Cu, Rh or Cr target or a radioisotope (Fe-55).

There are several options for fluorescence detection. Samples containing 0.1–4.0% can be analyzed with a nondispersive (radioisotope) or energy dispersive detector (ASTM 4294).[5] Instruments are calibrated frequently with sulfur in resid reference samples. While large amounts of heavy metals may interfere, the amount of iron, nickel and vanadium usually found in residual oils does not. The nondispersive and energy dispersive spectrometers are simple enough to be incorporated into portable instruments.

Lower levels can be measured at the sulfur K_α line at 5.373 Å with wavelength dispersive spectrometers (ASTM D 2622).[5] Sulfur levels from 0.0003 to 5.3% can be measured directly after the addition of an internal standard. The background intensity measured at a recommended wavelength of 5.190 Å (5.437 Å for a Rh target) is subtracted from the peak intensity. The resultant net counting rate is then compared to a previously prepared calibration curve or equation to obtain the concentration of sulfur in mass percent.

3.2 High-temperature Combustion and SO_2 Measurement

High-temperature combustion followed by SO_2 detection offers an alternative fast method for determining sulfur in resids without matrix-matched standards. In the combustion techniques, samples are burned under controlled conditions and the mixture of SO_x gases measured by titration or IR detection. ASTM D-1552[5] includes two types of combustion (tube furnace and induction furnaces) and two methods of measurement (iodate titration and IR detection of SO_2).

To achieve complete combustion of the refractory resid (high boiling, viscous and tendency to form coke), the samples must be burned "smoothly" to SO_2, i.e. without splatter, flash, or formation of coke. In the tube furnace combustion, a sample is weighed into a ceramic boat, MgO and V_2O_5 added as combustion accelerator, placed into the cool portion of the furnace, and a flow of oxygen established over the sample. The boat is then pushed

into the combustion zone set at 1371 °C (2500 °F) to produce SO_x where SO_x is ~97% SO_2. In the induction furnace combustion, samples are weighed into a ceramic crucible, covered with an inductor (powdered iron or tungsten) and accelerator (vanadium pentoxide). The crucible is covered and placed into an oxygen stream in the instrument where it is heated for 90 s by an induction coil.

For the titration measurement, the combustion products are passed into an absorber containing an acid solution of potassium iodide and starch indicator that is mounted on an autotitrator equipped with a photodetector. Initially, a faint blue color is established in the absorber solution by the addition of standard potassium iodate solution. As SO_2 is evolved, it bleaches the blue color and the autotitrator adds more iodate. The volume of standard iodate consumed during the combustion is a measure of the sulfur content of the sample.

For the IR measurement, the combustion products are passed through traps that scrub out CO_2, moisture and dust prior to IR absorption measurement. The area response of the IR absorbance is used to calculate the mass percent of sulfur for the sample weight. The IR calibration factor is determined using standards approximating the material to be analyzed. Accuracy is increased if standards bracketing the sample are also analyzed. The combustion techniques have comparable precision but are less convenient than XRF.[9]

3.3 Interferences

For XRF, errors in the sulfur determination can result when the elemental composition (excluding sulfur) of samples differs significantly from the standards. For example, differences in the carbon–hydrogen ratio in sample and calibration standards induce errors in the determination. Compensation is commonly made by the addition of an internal standard or use of a standard addition technique. Because the distance between the sample and detector affects the response, the Mylar® on the cell must be flat, the sample must be free of sediment (or diluted with solvents that do not induce asphaltene formation), and "infinitely thick" (>15 mm) for consistent excitation. For combustion tests, the iodate titration can be affected by >1% chlorine and >0.1% nitrogen, while IR detection will tolerate somewhat higher concentrations.

3.4 S Speciation

Both wet chemical and instrumental techniques show that sulfides and thiophenes are the major sulfur types in resid. Characterization studies of the deep distillates suggest that both types are present within the multiring structures in atmospheric and vacuum resids. Iodate titration and iodine complex tests show that the fraction of sulfur as sulfide decreases as resid boiling point increases.[10,11] Roughly two-thirds of the sulfur in atmospheric resid is estimated to be thiophenic by a variety of techniques: iodate titration,[12] by NMR (nuclear magnetic resonance) measurements after derivatization,[13] excited X-ray absorption fine structure (EXAFS),[14] and X-ray absorption near edge spectrometry (XANES).[15] Selective reduction experiments suggest that the sulfides in resid exist in links between multiring structures as well as in the rings.[16] Sulfoxides detected by XPS (X-ray photoelectron spectrometry) may be limited to the thin layer (<10 molecules) sampled by this technique. Other advanced analytical techniques for elucidating the structure of sulfur species in various fossil resource materials have been reviewed.[17]

4 DETERMINATION OF NITROGEN IN PETROLEUM RESIDUE

4.1 Measurement Techniques

Nitrogen in resid is commonly measured by two techniques. The classic Dumas technique is used for samples containing >0.2% nitrogen; for samples containing less, nitrogen can be measured down to 0.004% by combustion and NO_x chemiluminescence (ASTM D 5762).[5] Other N-measurement techniques are not well suited for the analysis of the forms and concentrations of N found in resids.

The Dumas technique is based on high temperature combustion, gas scrubbing, and reduction of nitrogen oxides for measurement as N_2 (ASTM D-5291 Method C). It is applicable to samples containing N between 0.1 and 50% N, irrespective of the form of nitrogen. In modern instruments, a sample is weighed into a tin capsule, combusted in oxygen (as O_2) at 1700 °C, and then the gases produced are swept through a train of gas-treating tubes with a helium carrier gas into a ballast reservoir. The gas treaters include chromic oxide (oxidizer) and silver-coated cobalt oxide (trap for halogens and sulfur). The scrubbed gases (CO_2, H_2O, NO_x) then are passed over copper at 650 °C to reduce the NO_x gases to molecular N_2. This mixture is then carried through molecular sieves to remove water and through supported magnesium perchlorate to remove CO_2. The N_2 in the He gas is detected with a thermoconductivity detector.

In the chemiluminescence test for resid, a boat inlet system is used. The sample is placed on a boat at room temperature, the boat placed in a combustion tube, and a flow of oxygen–argon established. The boat is advanced into a high-temperature combustion tube where the nitrogen is oxidized to nitric oxide (NO) that

is then allowed to react with ozone creating an excited form of nitrogen dioxide.[5] The light emitted when the excited NO_2^* decays is detected by a photomultiplier tube and the resulting time-integrated signal is a measure of the nitrogen contained in the sample. The detector is calibrated with model nitrogen compounds. Although the scope of the test can cover the 1–1000-wppm range the linearity of the detector is much more limited. Good laboratory practice would suggest using a calibration curve with nitrogen contents close to the range of the samples being analyzed.

4.2 Interferences

The Dumas and chemiluminescence methods are generally free of interference. Assuming that a representative sample has been taken and is within the calibration range of the methods, these analyses can be applied to most resids. As long as the sample is soluble in the mixed solvent used for the titration, the basic nitrogen in resids can also be measured routinely.

4.3 N Speciation

Deep HVGO (heavy vacuum gas oil) distillate data suggest that the most common nitrogen compound types in resid are pyrrole and pyridine benzologs.[7] Dilute solutions of resid in deuterochloroform detect the pyrrolic N–H at 3650 cm^{-1}.[18] NMR studies after derivatization with strong base and labeled methyl iodide confirm the presence of that structure. This ''acidic nitrogen'' accounts for roughly two-thirds of the total.[19] Basic nitrogen titrations suggest similar ratios of these two main nitrogen types.[20] Fourier transform infrared (FTIR) and titration data indicate the presence of amides in some resids.[21] No evidence is found for alkyl or aromatic amines in resid.

5 DETERMINATION OF METALS IN PETROLEUM RESID

5.1 Measurement Techniques

Nickel and vanadium are present as organometallics in crudes at levels characteristic of their geochemical environment.[1,2] Although sodium and iron are also commonly measured in resid, these metals are more likely to be present as entrained brine (Na) or scale and soluble corrosion products (Fe). Other metals have been found in soluble form at trace levels (<0.1 ppm) and at higher levels in the form of entrained brine or corrosion products (scale). The metals in resid can be measured by a number of instrumental techniques, among them XRF, flame atomic absorption (FAA), graphite furnace atomic absorption (GFAA), inductively coupled plasma atomic emission spectrometry (ICPAES), and instrumental neutron activation analysis (INAA).[22,23]

5.1.1 X-ray Fluorescence

The direct XRF techniques used for sulfur can be applied for Fe, Ni, and V if the metal concentrations are >10 ppm. XRF has poor sensitivity for Na. Although XRF has been reported to measure trace metals after acid digestion, precipitation and filtration, the results appear erroneously high.[24]

5.1.2 Flame Atomic Absorption

In FAA, a sample is aspirated into a laminar acetylene–air or acetylene–nitrous oxide flame. The emission lines of the element to be measured (produced by a hollow cathode lamp) are focused through the flame into a spectrometer that measures the absorption of one of the characteristic lines. Corrections are made for background absorption using Zeeman effects or using broad band absorption from a deuterium lamp. Peak heights are measured and results quantified using standards prepared in similar matrix types.[25]

Both direct and indirect FAA methods have been included in standard methods for the determination of Ni, V, Na, and Fe in crude oils and residual fuels by FAA (ASTM D 5863).[5] In the direct method, samples are diluted to 5 to 20% in an organic solvent (xylene or tetralin), depending on the anticipated metal content. Separate analyses are made for sodium (589.0 nm), iron (248.3 nm), and nickel (232.0 nm) as they are aspirated directly into an air–acetylene flame. Concentrations are calculated from calibration curves prepared in the same manner using oil-soluble metals standards. Vanadium is analyzed at 318.4 nm using a nitrous oxide–acetylene flame with 15-ppm Al (oil-soluble standard) added as an ionization suppressant. The dilution, needed to minimize the effect of resid matrix, limits direct FAA to Ni, V, Na and Fe.

In contrast, the matrix is destroyed in the indirect method. Samples of 1 to >20 g can be wet ashed with sulfuric acid and the ash taken up into a dilute nitric acid solution. The solution is then analyzed for each element separately by FAA at the same wavelengths as the direct method. For vanadium, 250-ppm Al is added to suppress ionization and measurements made with a nitrous oxide–acetylene flame. Concentrations are determined from calibration curves in the same aqueous acid matrix.

5.1.3 Graphite Furnace Atomic Absorption

In GFAA, a hollow graphite tube furnace in an inert gas atmosphere is mounted in the optics of an atomic absorption spectrometer. A sample is introduced into

the furnace. The tube is heated (by electric resistance) through a sequence of drying (100–300 °C), ashing (600–1500 °C) and atomization (up to 3000 °C) stages. During the atomization stage, the peak height is measured and corrections made as in FAA. It is not possible to give specific heating cycles because the optimum conditions vary from element to element and between instrument designs. In indirect GFAA, where the samples are ashed prior to injection, the generic (aqueous-based) detection limits for GFAA are generally lower than for FAA, but actual values differ between instruments.[25]

GFAA has also been applied to the direct analysis of metals in crude oils after dilution with toluene or xylene.[26] Nickel measurements are routine; vanadium requires addition of some ashing aid (toluene sulfonic acid, for example) to avoid losses of vanadyl species by volatilization.[27] Some trace metals have been measured by direct GFAA, but each analysis requires optimization of the heat cycles.

5.1.4 Instrumental Neutron Activation Analysis

INAA can be used to measure the metals as a survey technique.[28,29] In INAA, a representative sample is sealed in an inert polyethylene capsule. The capsule is then pneumatically conveyed into a nuclear reactor where it is exposed to a high-intensity neutron flux (for example, 5×10^{12} n cm^{-2} s^{-1}) for a predetermined time (5 min to 8 h). After irradiation, the capsule is moved to a shielded detector until the background emission from short halflife isotopes has decreased sufficiently to allow the elements of interest to be detected. Radiation from the capsule is measured for 3 min to 10 h by a γ-ray spectrometer equipped with a lithium-drifted germanium crystal detector (Table 6).

Table 6 Irradiation conditions for selected nucleotides measured by INAA

Irradiation time (@ 5×10^{12} n cm^{-2} s^{-1})	Measurement time (minutes)	Nucleotide measured	Detection limit (ng g^{-1})
5 min	3 min	^{28}Al	NR
		^{27}Mg	NR
		^{52}V	2
5 min	20 min	^{56}Mn	15
8 h	80 min	^{76}As	5
		^{24}Na	20
		^{42}K	NR
8 h	10 h	^{51}Cr	20
		^{59}Fe	50
		^{58}Co (for Ni)	100
		^{75}Se	10
		^{65}Zn	25

NR = not reported. From Filby and Olsen.[28]

5.1.5 Inductively Coupled Plasma Atomic Emission Spectrometry

In ICPAES, a sample solution is pumped into a 10 000-K argon/oxygen plasma torch. At this temperature, all the organics are destroyed and the metals converted to excited atoms and ions. The emission from the torch is dispersed by a spectrometer onto an array of photodetectors positioned to measure one of characteristic atomic emission lines of the selected elements. Results are determined from calibration curves using external standards. Each ICPAES spectrometer is unique in design, selected wavelengths, and computer capabilities; suggested emission wavelengths are given in standard methods (ASTM D 5708).[5] All measured emission peaks are referenced to a specific element added as internal reference.

In ASTM D5708 (Method A),[5] ICPAES is used in a direct method that measures Ni, V, and Fe. In the method, a sample is diluted to 10% (w/w) with xylene or tetralin. Results are determined from calibration curves using standards in a white oil diluted with the same dilution solvent. The direct ICPAES method is modified slightly for use in measuring trace metals (Ag, Al, B, Ba, Ca, Cd, Cr, Cu, Fe, Mg, Mn, Mo, Na, Ni, P, Pb, Si, Sn, Ti, V, and Zn). A sample is blended with an internal reference (Co) to correct for viscosity effects. Typical working ranges are in the 0.05–10-ppm range.

In the indirect ASTM test for Ni, V, Fe, and Na (D5708-Method B),[5] resid samples are combined with sulfuric acid in a beaker and heated to dryness on a hot plate to char the sample and convert the metals to sulfate salts. The beaker is then placed in a muffle furnace at 525 °C overnight to burn off the char. The inorganic residue is digested with nitric acid and evaporated to incipient dryness. The contents of the beaker are then dissolved in dilute nitric or hydrochloric acid, the solution made to volume, and the metals quantified by ICPAES using aqueous calibration standards. Detection limits vary with the size of sample used and the spectroscopic sensitivity of each metal to be measured. Metals measured by this technique differ slightly from the direct technique (Al, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, Pb, Sb, Tl, V, Y, Zn, and Zr).

5.1.6 Inductively Coupled Plasma Mass Spectrometry

Inductively coupled plasma (ICP) capabilities have been expanded and detection limits lowered by the introduction of inductively coupled plasma mass spectrometry (ICPMS).[30,31] The latter combines ICP excitation with mass spectrometric detection. In this mode, the ICP torch generates a cloud of ions that are accelerated into a mass spectrometer that resolves the excited atoms. Because the torch also destroys the sample matrix, ICPMS can be applied directly to oil samples dissolved

in xylene. In addition to dilution with solvent, resids have been analyzed by ICPMS in the form of aqueous microemulsions.[32] Both internal standard (Bi, Sc, etc.) and standard addition techniques have been used for quantification.[22] If samples are ashed and analyzed in diluent aqueous acid, the ICP methods have even better sensitivity and are less subject to interference.[33] However, care must be taken to avoid Cl (brine salts, methylene chloride or HCl) because the ClO formed in the torch interferes with the measurement of V at mass 51.

5.1.7 Choice of Metals Method

Trace metals can be measured in resid by many of the above techniques. Nickel and vanadium in resids can be determined rapidly by XRF at levels above 10 ppm. Many of the FAA and GFAA techniques developed for individual trace elements in the 1970s are still in use. Where applicable, direct GFAA affords the fastest technique for determining an individual element. For greater accuracy and sensitivity, indirect FAA and GFAA remain the methods of choice for individual elements.

Multielement survey data can be collected on resid by INAA and ICP techniques that use expensive specialized instrumentation. ICP methods have largely supplanted INAA for survey measurements of trace elements because they have lower detection limits for most elements. Direct ICPAES can be used to rapidly screen soluble metals; the indirect version can be more sensitive and can quantify suspended metals. The same restrictions apply to ICPMS which has several orders of magnitude more sensitivity for many elements. INAA and ICP results for Fe, Ni, and V are in excellent agreement with other techniques. However, the advantages of INAA (multielement, simplicity of sample preparation, minimal matrix effects, few interferences) are balanced by long analysis times caused by decay periods and specialized training needed for working with reactor and radioactivity.

5.2 Sample Preparation

5.2.1 Sampling

Crude oils are produced with varying amounts of water (actually salt-rich brines) and sediment; traded crudes always carry some portion of these nonvolatile impurities. Distillation leaves sediment and (now dry) salts in the resid. After desalting, uptake of corrosion scale and addition of process aids, the refinery resid differs from the laboratory resid obtained by distillation of a crude oil that retains the sediment and dry salts.

In comparison with Ni and V, trace metal analyses show wide discrepancies. The variations among reported values appear to be related to sample homogeneity and preparation technique rather than the detection system. This has been reinforced by a systematic study of trace metals in whole crudes that shows natural metals concentrations two orders of magnitude lower than reported elsewhere. A statistical evaluation of the data scatter suggests that many of the trace metals are associated with contamination in transportation or with suspended sediment and water.[34,35]

For accurate trace metals analyses of a submitted sample, relatively large portions of resid should be taken as a heterogeneous material after thorough mixing. Resids can be mixed after heating to a free flowing liquid or as a dry powder after freeze-fracturing with dry ice.

5.2.2 Direct Methods

The physical properties of resid can play a significant role in the direct analysis of metals in resid. Inherently, the direct methods assume that the metals are homogeneously distributed in the resid sample. Because the resids are so dark, it is difficult to determine if sediments are present. If the metal is present as particulate (scale or salts from entrained brine), the direct techniques can give erroneous results. High results may be obtained in XRF if a metal-rich sediment settles onto the Mylar® window in the test cell; low results may occur if particulates escape the atomic absorption flame or ICPAES torch. Variability in direct analyses by ICP methods can arise from factors that influence the sample flow into the ionization region, especially viscosity, surfactants and choice of solvent, and calibration should be done with oils that closely match the sample matrix.

As noted above, metals can be lost in the dry ashing provided as part of the GFAA cycle. Published detection limits for aqueous solutions may not be achievable by direct GFAA analysis of resid samples. The severe ashing conditions required to minimize background interference from resids can volatilize some metals. This is particularly true of the Ni and V porphyrins in resids, but can also apply to the more volatile metals such as mercury, selenium, arsenic, cadmium, antimony and lead. To reduce the severity of ashing conditions and eliminate metals loss, homogenous ashing aids (such as *p*-xylenesulfonic acid) can be added to the diluent.[24] The materials accelerate the destruction of the resid allowing lower ashing temperatures and also convert the metals into a microsulfated ash, i.e. sulfates and oxides that are less volatile than indigenous metal compound types.

5.2.3 Indirect Methods

Most heavy metals are not lost in wet ashing of resid. The exceptions, metals not readily oxidized or inherently

volatile as the oxide (Hg, Se, As, etc.), have been studied separately. The initial addition of sulfuric acid prevents losses of some metals if chlorides are present, for example V as $VOCl_3$. The sample should be well mixed with sulfuric acid and heated gently at first to avoid splatter. Numerous variations have been suggested for ashing samples for trace metals including alternate oxidizing agents, different acids for dissolution, and reagents for fluxing the sulfated ash. Microwave ashing has been substituted for the sample preparation of resid samples for metals analyses. In microwave ashing, the resid is combined with oxidizing acids (sulfuric, nitric, perchloric or mixtures thereof), sealed in Teflon™ vessel, and heated in a microwave oven for a brief period. The resulting solutions are washed from the vessel with aqueous acid, an internal standard added, and made up to volume. Because it uses concentrated heating in a closed vessel, microwave ashing is faster and less subject to contamination than sulfated ashing. On the other hand, their microwave techniques are limited to small samples and care has to be taken to avoid explosions with the sealed vessel. Thus, sulfated ashing, is preferred for routine analyses because it requires less technique and no specialized equipment.

5.3 Metal Speciation

The consistency of the Ni and V results among techniques demonstrates that these elements are homogeneously dispersed in the colloidal resid.[36] A portion of the metals can be measured by the Soret bands characteristic of porphyrins in the ultraviolet–visible spectra.[6,7] Although a larger fraction of the metals are described as ''nonporphyrin'' structures,[37,38] X-ray absorption fine structure (XAFS) analyses show that *all* the Ni and V resid is in molecular environments similar to those in porphyrins.[39,40] Thus, the nonporphyrins appear to be mixtures of closely related tetrapyrrole analogs. This direct spectroscopic evidence is more compelling than the indirect data (reactivity, size exclusion chromatography, ESR (electron spin resonance), etc.) from which alternate structures have been inferred. The lack of a Soret band for these metals may be rationalized by (i) molecular association of tetrapyrrole structures with electron-rich aromatics or heteroaromatics; (ii) a mixture of numerous isomeric porphyrin homologs with overlapping spectra, (iii) molecules with extended conjugation (benzoporphyrins), or a combination of all these.

Among the trace elements, Fe in resid can appear in both soluble (indigenous naphthenates and corrosion products) and insoluble (scale and iron sulfide) forms.[23] For accurate total iron measurements, indirect techniques should be used on well-mixed samples. Other trace metals in resid may also be present in either soluble or suspended form.[1,2] The suspended forms, arising from brine salts, probably contribute more to the trace metal load than soluble metals.[41] The latter are generally naphthenate soaps of basic metals (groups I, II, VIII).[23] Traces of elements that can form organometallics (As, Hg, Se, etc.) are found in crude, but rarely survive distillation.[42]

6 COMPARISON WITH OTHER "HEAVY OIL" MATRICES

Resids are often compared with other viscous black oils that are rich in trace metals and heteroatoms. Although some of these ''oils'' are extracts and others are pyrolyzates, they are lumped together because they represent a major hydrocarbon resource that challenges conventional crude oil processing. In most cases, the methods used for the analysis of resids can be applied to these alternate ''heavy oils''. The following briefly notes the characteristics of each type and the unique difficulties that each presents for the methods.

The elemental composition of oil sand bitumen falls generally into the range of petroleum resid with 1–10% S, 0.4–1.0% N and nickel and vanadium contents hundreds or thousands of parts per million. The higher molecular weight, viscous nature of these oils presents basically the same challenges as found for resids, that is, taking representative samples, avoiding solvent precipitation, and preventing coke formation prior to measurement. The analyses of S, N, Ni, V, and Fe in bitumen, extra heavy oils and tars have been widely reported.[6,7] Classic combustion techniques are routinely applied for S and N. Direct INAA or indirect ICPAES are favored for metals.[28]

Most of the techniques used for petroleum resids can be applied to shale oils with adjustment of sample sizes to keep within the instrumental calibration range.

Table 7 Heteroatom content of some raw shale oils[4] determined by different processes

Process	Paraho DH	Occidental MIS	Dravo	CSR
Shale Source	Colorado	Colorado	Kentucky	Australia
Nitrogen (wt%)	2.02	1.51	1.14	1.3
Oxygen (wt%)	1.38	0.65	1.97	1.3
Sulfur (wt%)	0.70	0.64	3.86	4.9
Iron (wppm)	53	45	110	55
Nickel (wppm)	2.4	6.7	–	3
Vanadium (wppm)	0.17	0.42	ND	153
Arsenic (wppm)	28	27.5	100	26

ND = no data or not determined.

Shale oils are rich in olefins, diolefins and nitrogen. The nitrogen-compound types that best survive the retorting conditions are nitriles, amides and pyrroles.[43] In presence of air, the latter combine readily with the olefinics to form sediments. Thus for quantitative analyses, shale oil samples must be protected from air. The boiling point distribution of heteroatoms of retort oils differs from petroleum resid. As a cracked product, the shale oil exhibits the decrease in sulfur concentration with boiling point while the concentration of nitrogen increases. Oxygen levels are typically higher than resid, but lower than coal liquids. Crude shale oils contain soluble forms of iron, nickel, and arsenic that can be measured by resid techniques.[44] Care must be taken to avoid losses of arsenic in volatile forms, however. Heteroatom contents of shale oils from a variety of sources show variability (Table 7):

1 INTRODUCTION

The goal of any manufacturing process is to make acceptable products in an economical fashion. To do this requires timely information about raw materials, material in process and product quality. It is the role of on-line analytical instrumentation in providing some of this information on crude oil, gasoline, and diesel fuel that will be addressed in this section.

2 ON-LINE VERSUS LABORATORY INSTRUMENTATION

Laboratory instrumentation sits in an environmentally controlled atmosphere and is operated by skilled people to provide information on samples collected from the process. The goal of both the on-line instrument and laboratory instruments sounds the same, that is, to provide information, but the conditions they must operate in are very different. The laboratory instrument has a skilled operator, whereas the on-line instrument must operate on its own. The laboratory instrument works on a sample that is extracted from the process line and normally cooled to room temperature and reduced to atmospheric pressure. The on-line instrument takes its own sample and works with it at line pressure and usually at line temperature. If any adjustments are required, the on-line system must make them as no operator is involved. This, of course, must be done by the sample system but the on-line instrument dictates what the sample system must do. One question that arises frequently is the need for temperature control of the sample. Near-infrared (NIR) spectroscopy is a tool which counts molecular bonds within the sample. As the temperature changes the number of molecules within a given path length changes and therefore the spectrum changes. In a system with very little hydrogen bonding, most of the changes can be accounted for with just the change in density. If hydrogen bonding exists, such as with water or alcohol, major changes in the spectra are noted with temperature differences. This need for temperature control can become a significant item for on-line instrumentation and is normally ignored in the laboratory because everything is at the same temperature, the temperature of the room.

3 NEAR-INFRARED SPECTROSCOPY – WHAT IS IT? OVERTONES?

Light can interact with matter in several ways:

1. Simple reflection – we see that every morning in the mirror.
2. Refraction – light as it changes mediums changes direction, for example, going from air into water (our eye glasses are shaped by this principle).
3. Ultraviolet light can be absorbed by certain molecules and has enough energy to move electrons into an excited state.
4. Infrared (IR) light can excite, stretching and bending the bonds that are dipolar.

In the NIR region of the spectrum, that band of wavelengths between visible light and the IR, or wavelengths from 700 nm to 3000 nm, light is able to excite overtones and combinations of some of the molecular bonds that are excited by the IR. The only significant absorbencies in the NIR are due to the hydrogen–X bonds where X is a heavier atom. Therefore, organic compounds where we have bonds between hydrogen and carbon, H–C, show bonds clearly in the NIR region. From the above, one might

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

think that all H–C bonds absorb at the same frequency and with the same intensity. However, this is not the case: just as in the IR range, there are many different bonds, depending on what else is attached to the carbon. For example, methyl bonds will differ from methylene bonds, which will be different again from aromatic hydrogen bonds.

NIR spectroscopy then makes use of the overtones and combination bands to analyze compounds in both quantitative and qualitative terms. Because of the complexity of the spectrum the qualitative aspect of NIR is played down but is used in judging raw materials for suitability in some manufacturing processes. By far the biggest use of NIR is in the quantitative area, not only for chemical make-up of the sample, but also for the physical properties of that sample such as boiling point.

How can the boiling point of a liquid be determined by shining light through it? From elementary physical chemistry we know that the boiling point of a mixture is determined by the mole fraction of each component in the mixture multiplied by the boiling point of each component. A mixture is not a static system. As it starts to boil, certain compounds evaporate first; this changes the composition so now the boiling point is higher. This process continues until all of the liquid has boiled. What could be done is to determine each component in the liquid, calculate its mole fraction and therefore its influence on the boiling point. By summing over all these components the boiling curve of the liquid could be determined. The NIR approach skips the step of identifying each component in the mixture but based on ''experience'' finds a pattern which will predict the boiling points of the liquid. This ''experience'' is called a model – a mathematical relationship between absorbencies at various wavelengths and the boiling points of the liquid. This ''modeling'' is one of the most powerful and frustrating aspects of NIR spectroscopy. It is frustrating in the sense that although the human brain cannot process the NIR spectrum into the underlying components, a computer, ''trained'' using various statistical methods, can. The methods start with a ''training set''. The spectra are collected for a set of samples which are similar to the samples expected to be used by the NIR instrument. Correlations are found between the wavelengths and associated absorbencies with the properties of interest. If these correlations involve very few wavelengths then we can use a method called multiple linear regression (MLR) to develop a ''model'' between the spectrum and the property of interest. More commonly many wavelengths are involved and we use methods such as partial least squares (PLS) or principal component regression (PCR). Both methods can use the entire spectrum and the difference is that PLS uses correlations between the property of interest and the spectrum to find the best fit and PCR uses the biggest spectral differences and tries to find correlations. (I have used PLS because that has worked the best for me where I have tested various methods.) Whatever mathematical tool is used, we call the resulting equation between the spectrum and the property of interest a model. One can apply various models to the same spectrum to determine various properties. In one refinery we are using 14 models to ''predict'' or measure the properties of the gasoline flowing through the NIR.

3.1 Warning

The above tools are extremely powerful and correlations will be found for any property of interest regardless of spectral information. Models should always be tested on a new set of samples, called the verification set, before the model is used. Since this new set of materials has not previously been analyzed by the spectrometer computer system, the results should indicate what will happen with future production samples. Note that the system can only measure samples within the calibration range of the instrument. If samples are outside the calibration range a new ''model'' must be constructed to incorporate the new sample types. Sometimes this involves a totally new model and sometimes the old model can be modified to include the new information. If the process has permanently changed, I recommend building a new model. If the old model did not cover the total range – then extend the model. I have seen different models used for winter and summer grade gasoline, for example, as well as a different model for each grade of gasoline.

3.2 Assessment of the Instrument

Why would one use NIR with the computer algorithms when IR is available? The biggest arguments for the use of NIR for liquid samples are: that sources are more stable; the detectors are easier to work with and more stable; windows are more sturdy (glass vs. salt plates); the path lengths for liquids are much more reasonable (mm and cm in the NIR compared with 0.1 mm or less in the IR); and fiberoptics are readily available in the NIR, at lower cost compared to IR fibers. The IR has a major advantage in the laboratory setting in ease of interpretation of the data; however, in the process environment, where very similar samples are seen minute after minute, for many days, it is the quantitative ability of the NIR that wins over the qualitative advantages of the IR region.

The statement that fiberoptics are readily available in the NIR region needs comment. There are many vendors who supply fibers for the communication industry that operate in the NIR region. In the communication industry the signal is either off or on; by contrast, for the analyzer industry we need to quantitate the size of the signal. In the

communization industry, certain wavelengths are chosen which fit well with the existing fibers, but in the analyzer industry we are using the wavelength range. The point is that fibers designed for the communication industry may not, or more probably will not, work for the analyzer.

3.3 Examples of Problems with Fiberoptics and How to Address Them

Figure 1 is a superimposition of two different pictures. In each case we have 10 m of fiber connected to a power meter. The difference is that at the bottom the fiberoptic coil is covered with black felt. The readings on the power meter tell the story: on the top where light is hitting the fiber, the reading is 389.7 and on the bottom with the fiber covered, the reading is 8.8. What is happening? Light is going through the fiber jacket and coupling into the fiber and that is what the power meter is reading. Once the problem is defined, there is an easy solution: to make the jacket out of material that does not transmit light in this region of the spectrum.

Figure 1 Comparison of light transmission in coated and uncoated fiberoptic coils.

The following is taken from a 1992 Eastern Analytical Symposium talk by G.H. Vickers of Amoco.

Figure 2 shows a standard drawing of an optical fiber. The assumption is that the light turns at the interface between the core and cladding and does not penetrate into the cladding. Figure 3 shows the spectrum of 10 m of plastic-clad silica fiber. The large absorbances are from the plastic cladding CH bands. This fiber is not usable in the NIR region. Figure 4 shows the spectra of a silica-clad, low OH, silica fiber with a Tefzel® jacket as a function of temperature. Note the large changes around 1400 nm. This is due to the change in the hydrogen bonding around the few remaining OH groups in the silica fiber. Also note the bands around 1250 nm and others of similar size. They are due to the CH bonds in the Tefzel® jacket. The cladding jacket is acting like a secondary fiber and becomes a plastic-clad silica fiber. How can this be avoided? Use a jacket material of high index of refraction to extract the cladding modes. The success of this is shown in Figure 5, where we have a silica fiber with a

Figure 2 Total internal reflection in an optical fiber.

Figure 3 Absorbance spectrum for a plastic-clad silica fiber.

Figure 4 Absorbance spectra of a silica-clad silica fiber with Tefzel® jacket at temperatures from 5 °F to 125 °F.

Figure 5 Absorbance spectra of a silica fiber clad with polyimide at temperatures from 5 °F to 125 °F.

silica cladding jacket with polyimide. Note the scale: other than the 1400 water peak, the spectra show changes of less than 0.005 AU. To eliminate this remaining difference we coil the fiber inside the jacket to allow for differences in thermal expansion of the fiber and the jacket as the temperature changes. In other words for fiberoptics to be usable in NIR requires some thought and understanding of the physics of the fiber. Unfortunately, all of the things mentioned to make the fiber useful add to the cost of the fiber.

It was mentioned previously that the optical path length through the cell in the NIR has a range from millimeters to centimeters. The NIR spectral region can be further subdivided according to the C–H vibration overtone. The higher the overtone the shorter the wavelength and the longer the path length for an equivalent absorbance. In general we can use a path length about a factor of 10 longer for each overtone. Therefore, in the first overtone region the path length is about 1 mm, in the second about 1 cm, in the third about 10 cm. With the 10-cm path the sample needs to be free of scattering particles or that effect will dominate the spectrum. There is another problem with the third overtone which must be discussed: interference from the ultraviolet and visible spectrum.

Certainly, most crude oil is black, but not all. The black color is due to the asphaltenes that are present in most crude oils. The peak absorbence of asphaltene is down in the ultraviolet part of the spectrum but the tail of the peak is so large that it extends through the visible and the third overtone of the NIR. However, if one examines the second overtone region, information on the olefin, aromatic and saturate content of the crude oil is available. Some work has been done trying to measure the sulfur and metals content of the crude oil but the results are questionable.

In the mid-1980s, Dr Jim Callis (University of Washington, as part of a project for the Center of Process Analytical Chemistry, CPAC) showed that octane numbers of gasoline (see section 3.4) could be determined from the NIR spectrum. The oil companies that were part of CPAC were skeptical of Dr Callis' results but realized the enormous impact they could have if proved to be real. Several companies undertook their own projects to test Dr Callis' work. The private work confirmed his original data and showed that the octane numbers could be obtained in all three overtones. However, additional effort also showed the sensitivity of the results to wavelength long-term reproducibility. By that I mean, if a model was developed and the spectrometer's wavelength axis drifted, the model's results were meaningless. In order to avoid the inherited drift in the moving grating spectrometers, two avenues were pursued. BP and Bomen worked together to develop the TOP-NIR which is a Fourier transform (FT)–NIR instrument. EXXON and Analect Instruments also developed an FT–NIR approach. Amoco and Perkin-Elmer developed a third overtone diode array system, the PIONIR 1024. Both the FT and the diode array approaches avoid the variation caused by the moving grating but introduce other problems which must be accounted for. With the diode array concept, dimensional stability is vital – hence the spectrograph temperature is controlled within 0.5 °C as the outside temperature varies from −40 °C to 50 °C on the PIONIR 1024. With the FT approach, mirror movement is referenced to a laser wavelength to ensure stability. All three systems have proprietary systems built in to give the required stability on the wavelength and absorbance axis to make the octane measurements.

A report in *Oil & Gas Process International*, 1997, by Kjell Arne Ulrund of Statoil, Norway, reports that

in addition to the octane numbers, they are measuring the MTBE (methyl tertiary butyl ether) concentration, olefins, benzene, initial boiling point, final boiling point and distillation evaporated at 70, 100 and 180 °C, every minute, using the PIONIR 1024. This system allows the operators, either human or computer, to optimize the gasoline blends using materials available in the refinery. The speed of the data allows on-line blending into ships for transport of the fuel.

3.4 Octane Numbers

There are three octane numbers: the Research Octane Number (RON), the Motor Octane Number (MON), and the Pump Octane Number (PON), which is the average of RON and MON. The traditional way to determine the RON and MON is with an engine and compare when the test fuel ''knocks'' in the engine compared to the standard. The standard is a blend, for MON, of iso-octane (2, 2, 4-trimethylpentane, octane number 100) and *n*-heptane (octane number 0). The MON is determined by finding a composition of iso-octane and *n*-heptane that knocks the same as the test fuel under the conditions of the test. It reflects the normal engine requirements at idle conditions. The RON is again determined by an engine test but the conditions simulate an engine under load. More severe conditions require a higher standard and that is toluene, octane number 113. The RON then finds the ratio of *n*-heptane, iso-octane and toluene that has the same knock properties as the test fuel under these new conditions.

Both the RON and MON tests have significant reproducibility problems and require highly trained operators to obtain consistent results. (I have been told that it takes about five years to train someone to correctly run the knock engines.)

Since the octane properties are related to the chemical composition of the fuel, maybe it is not too surprising that the octane number could be determined by the NIR. However, when one considers that a typical gasoline is a mixture of over 250 compounds it is amazing that a 5 to 10 factor PLS will allow determination of the octane number from the NIR spectrum.

3.5 Determination of Methyl Tertiary Butyl Ether

The standard way to measure MTBE in gasoline is with a long, 40-min, gas chromatography (GC) procedure. A 40-min analysis may be acceptable in a laboratory but consider a refinery that is blending 1 million gallons per hour (a single large gasoline refinery). What is that refinery to do? It must put in at least the minimum legal level of MTBE. If the GC analysis is not available until 40 min after analyzing, the refinery must hold that 1 million gallons of gasoline waiting for results or put in enough MTBE to make sure it has the legal minimum. With the NIR report results every minute, the ''excess'' MTBE can be reduced.

How can the NIR measure the ether concentration? Because of the electronegativity of the oxygen, the hydrogens on the carbon adjacent to the oxygen will absorb light at a slightly lower wavelength (higher energy). It is that shift which can be measured.

3.6 Olefins

Olefins are very reactive compounds and at very high concentrations are used to make polymers, e.g. polyethylene. In gasoline they are blamed for gum formation in the fuel system, and as components in the formation of smog if they escape from the system.

The standard method for determination is called fluorescence indication analysis (FIA) (do not confuse with flow injection analysis, also referred to as FIA). The FIA procedure involves flushing the sample down a silica gel column which has been impregnated with indicators; as the gasoline flows through the column, colored bands will show the paraffins, isoparaffins, aromatics, nathphenes, and olefins in the gasoline. Again, this is a very slow test that is nonrepeatable. Factors associated with the lack of repeatability are the column packing, flow through the column, sample size, and the indicator preparation. This is very different from shining light through the sample, as is done with the NIR method.

4 ACCURACY AND REPEATABILITY

Several times the standard tests have been referred to as nonrepeatable, yet these are the standards which are used to calibrate the NIR. How can the NIR do better? There are two different issues to consider: repeatability and accuracy.

The NIR is extremely repeatable in determining the absorbance vs. wavelength, the spectrum values, on an acceptable unit. The model which coverts such data to information, such as octane number, is just a multiplier, a set of numbers. Hence it is totally repeatable. Therefore, the NIR system will give the same answers on the same sample regardless of how many times it is run.

The accuracy of the NIR opens up a totally new argument. One side of the argument says that the NIR cannot be more accurate than the standard, whereas the other side says that if we have enough samples in our calibration set the *random* errors of the standard method will be averaged out and therefore the NIR is more accurate (closer to the truth) than the standard model. Unfortunately, while I side with the second argument,

Table 1 Expected PIONIR performance for diesel/gasoline

Property	Units	Typical range	ASTM method	Repeatability		ASTM reproducibility	SEP		Notes
				ASTM	PIONIR		ASTM	PIONIR	
Cetane number	CN	40 to 56	D613	0.7	0.11	2.9	1.0	1.2	ASTM values at 48 CN
Cetane index (2-term)	CN	40 to 56	D976	N/A[a]	0.12	N/A		0.8	Correlated ±2 CN to engine rating, per method
Cetane index (4-term)	CN	40 to 56	D4737		N.M.[b]			0.8	ASTM values depend on D86 and D1298
Aromatics	vol%	10 to 50	D1319	1.5	0.2	3.3	1.2	2.0	ASTM values at 35% aromatics
Saturates	vol%	48 to 88	D1319	1.7	0.2	5.3	1.9	2.0	ASTM values at 65% saturates
Kinematic viscosity	cSt	1.480 to 3.530	D445	0.1365	0.0240	0.4200	0.1516	0.14	ASTM values at 2.5 cSt
Specific gravity	Gms/me	0.8090 to 0.8710	D1298	0.0005	0.0003	0.0012	0.0004	0.0016	
T10	°F	364 to 478	D86	5.4	1.3	12.6	4.5	9.5	ASTM values for automatic method, slope 2.7
T50	°F	418 to 561	D86	5.4	1.2	15.3	5.5	5.6	ASTM values for automatic method, slope 2.7
T90	°F	476 to 644	D86	5.4	2.3	12.6	4.5	10.3	ASTM values for automatic method, slope 3.6
R250	%	8.5 to 29.5	D86	1	N.M.	3	1.1	1.5	ASTM values for slope 1.5
R350	%	87.0 to 98.0	D86	1	N.M.	2	0.7	1.6	ASTM values for slope 2
Flash point	°C	56 to 86	D93	5	1.0	10	3.6	3.6	ASTM value for automatic method
Cloud point	°C	−8 to +4	D2500	2	0.4	4	1	2	
Pour point	°C	−35 to +10	D97	3	0.4	6	2	5.4	

On-line customer results can typically be more accurate than the general results reported here when calibration models are developed for the customer's specific type of fuel. Calibration model results will depend on the laboratory analysis of the samples using the primary method. Note that the ASTM (American Standard Testing Method) SEP (standard error of perdition, measured on samples not in modeling set) is defined as the reproducibility reported in the method divided by 2.77 and that the PIONIR (Orbital's third overtone NIR instrument) repeatability data are based on 120 repeated scans of a static sample over 48 hours.

[a] Not applicable.

[b] Not measured.

the ''jury is out'' on this entire issue. The problem is that even if the NIR is more accurate on a given sample than the standard method, there is no way to prove it with *one* laboratory test.

5 DIESEL

Another major product of most refineries is diesel fuel. Although there are no literature references to the NIR applications for diesel, the system can be used to determine:

1. Cetane number
2. Cetane index
3. Aromatic concentration
4. Saturate concentration
5. Viscosity
6. Specific gravity
7. T10 (temperature at which 10% of the fuel has been distilled off)
8. T50
9. T90
10. R250 (amount distilled off at 250 °C–note the use of °C vs. °F in T-numbers)
11. R350
12. Flash point (temperature in °C at which fuel supports a flame)
13. Cloud point (temperature at which fuel becomes cloudy, in °C)
14. Pour point (temperature at which fuel will not pour, in °C).

The cetane numbers are measures of fuel quality for a diesel engine like octane numbers are for the gasoline engine. Because of the extreme difference in ignition methods of the two engines, the octane numbers and cetane numbers are almost anti-correlated – straight chain molecules have a low octane number and high cetane number.

The cetane index measures how the fuel will respond to certain additives, cetane improvers – vital information so the refiner can put in the correct amount of additive. The cloud point and pour point are important values but difficult to obtain in the laboratory because of the time and operator attention required to get repeatable results.

The results using one type of NIR instrument available from Orbital Sciences are shown in Table 1.

6 CONCLUSION

What the above has shown is that the NIR spectrum contains valuable information to optimize the refinery operation. One large refinery gave the NIR credit for adding 40 million dollars to the ''bottom line'' in the first year of operation. This saving resulted from fast, precise, and, this refinery believed, accurate results of the NIR.

ABBREVIATIONS AND ACRONYMS

FIA	Fluorescence Indication Analysis
FT	Fourier Transform
GC	Gas Chromatography
IR	Infrared
MLR	Multiple Linear Regression
MON	Motor Octane Number
MTBE	Methyl Tertiary Butyl Ether
NIR	Near-infrared

Nuclear magnetic resonance (NMR) spectroscopy is a powerful analytical method for determining the structure of an organic material. Developments in NMR have allowed high-resolution spectra of materials in the solid state to be obtained. Thus, materials that have been intractable, such as kerogens and sedimentary organic matter, can now be characterized for their organic carbon structure. The combination of solid- and liquid-state NMR makes NMR one of the most useful methods for the characterization of petroleum and its products.

Petroleum is formed from the maturation of sedimentary organic matter as a result of burial over geological timescales. Everyone is familiar with the products of petroleum, i.e. gasoline, diesel fuels, chemicals, and so on. All these materials, including the petroleum source rock material, can now be studied by NMR, from the genesis of petroleum to finished products such as transportation fuels. In this article, some applications of solid- and liquid-state NMR to the characterization of petroleum source rocks and petroleum end products are described.

1 INTRODUCTION

1.1 Scope

In an encyclopedia article such as this, which deals with NMR studies of petroleum and related materials, it is not practical to cite and discuss all the applications of NMR to the analysis of petroleum. This would require a great deal more space and the article would be more of a textbook or review-type article than an encyclopedic article. Consequently, the applications are necessarily limited, as are the citations for a given topic. It is hoped to provide sufficient information here for the reader to obtain an appreciation of the uses of NMR in petroleum analyses, or to give sufficient citations to direct the reader to more detailed information about a particular application.

The applications range from the maturation of petroleum source rocks to the end-use of petroleum as distillate products, and include solid- and liquid-state NMR applications. For a more detailed discussion of NMR techniques, the reader is referred to the *Related Articles* section at the end of this article for additional reading on **Solid-state Nuclear Magnetic Resonance** and liquid-state NMR (**Carbon-13 Nuclear Magnetic Resonance Spectroscopy**). Only a rudimentary discussion is included here. The objectives are to introduce the analytical application of NMR to the researcher who wishes to acquire an understanding of some of the methods and terminology that are most often encountered in the literature.

1.2 Historical Development

The possible applications of NMR to the characterization of petroleum and petroleum products were first discussed in 1955 and the first reports of the use of ^{1}H NMR were published in 1957 as discussed in Retcofsky et al.[1] Quantitation of the elemental hydrogen content of petroleum materials using ^{1}H NMR was reported in 1959[2] and the first quantitative ^{13}C NMR spectrum of a petroleum fraction by a time-averaged slow passage technique was reported in 1967.[3] It was not until 1976, shortly after the development of Fourier transform NMR, that quantitative ^{13}C investigation of crude oils and petroleum products started to become routine.[4]

The development of solid-state NMR techniques of cross-polarization (CP) and magic angle spinning (MAS) with high-power decoupling in the mid 1970s provided a great advance in characterizing and understanding the chemical nature of the organic matter in sedimentary rocks. These techniques provide information about the carbon structure of the organic matter in the rock without the need for preparation of kerogen concentrates. Some of the first published CP and CP/MAS ^{13}C NMR spectra were of coals[5,6] and oil shales,[7,8] materials that are largely insoluble and for which few good techniques then existed for probing the carbon structure of these fossil fuels.

2 SOLID-STATE NUCLEAR MAGNETIC RESONANCE CHARACTERIZATION OF PETROLEUM SOURCE ROCKS

2.1 Experimental Procedures and Instrumentation

Sample preparation in solids NMR is relatively straightforward. The sample must be ground to a sufficiently small particle size, so that the NMR spinners can be packed uniformly in order to spin the samples at high speeds without difficulty. A 100-mesh sample size is ideal because this particle size is acceptable for elemental analyses (C, H, O, N, S) as well. Larger particle sizes can be used. The criteria are that the spinner can be balanced to spin easily and that the sample placed in the spinner is representative of the material under investigation. The sample should be free of magnetic materials. In situations where there is not enough sample material to fill a spinner, or the particle size leads to an unbalanced spinner, other materials such as sulfur, or salt (NaCl) can be added to provide ballast to the spinner. Salt works well because the sample material can be recovered easily by washing. This is especially useful for kerogen samples, which are usually prepared in small quantities.

A field of 2.3 Tesla (100 MHz for ^{1}H, 25 MHz for ^{13}C) is about optimum for solid-state NMR measurements on solid fossil-fuel materials including source rocks. At this field strength, spinning rates up to 5 kHz can easily be obtained for spinners of 7.5-mm diameter. In addition, large-volume spinners with diameters of about 14 mm can also be spun at rates of about 4 kHz.[9] These rates are sufficient to minimize interferences caused by spinning sidebands associated with the chemical shift anisotropy. The increased sample size of a large-volume spinner has the advantage of increasing the signal-to-noise ratio (S/N), all other parameters being equal. For example, a typical 7.5-mm sample spinner has a volume of ca. 0.5 mL. A large-volume spinner has a volume of ca. 2.25 mL. Obviously, the greater the sample size, the shorter the time required to obtain a spectrum with a given S/N.

A variety of compounds have been mixed with oil shale and coals as internal standards to determine the percentage of carbons observed in CP and single-pulse NMR measurements.[10–14] In some cases, the spinner material, Delrin®, has been used as an internal standard.[9] An excellent reference material is *tetrakis*(trimethylsilyl) silane (TKS).[11,12] Furthermore, treatment with samarium(II) iodide has been shown to selectively reduce the free radical content, which in turn leads to an increase in the percentage of observable carbon.[12] For example, treatment of Wyodak sub-bituminous coal with samarium(II) iodide increased the percentage of observable carbons by 27%, leading to an increase in the carbon aromaticity of ca. 10% from 0.66 to 0.73. This technique should work on petroleum source rock samples, although it has yet to be tried on these types of sample.

The issue of quantitation in CP has been recognized since the beginning of its application to fossil fuels.[15–21] The main concerns are whether all carbons are observed equally in the CP experiment, and whether the fraction of carbons observed are a faithful enough representation so that the small loss of signal from carbons that are not observed can be ignored. Other concerns relate to such things as sample heterogeneity, spinning sidebands, unpaired electrons, MAS, and the pulse repetition rate. The problems associated with quantitation of ^{13}C NMR measurements in carbonaceous solids have been reviewed.[21]

2.2 Nuclear Magnetic Resonance Measurements of Solids

2.2.1 Cross-polarization with Magic Angle Spinning

CP NMR relies on the presence of an abundant spin system (^{1}H) to enhance the observation of a signal from a dilute spin system (^{13}C). The idea is to transfer polarization (and hence signal intensity) from the abundant ^{1}H spins to the dilute ^{13}C spins.[22] CP is a technique that enhances the sensitivity by a factor of four over the conventional single-pulse method. The

CP experiment consists of four basic timed sequences of radiofrequency (RF) pulses. The four-part procedure consists of (1) polarization of the ^{1}H spin system, (2) spin-locking in the rotating frame, (3) establishment of $^{13}C-^{1}H$ contact, and (4) observation of the ^{13}C free-induction decay (FID). CP/MAS NMR is discussed in greater detail in **Solid-state Nuclear Magnetic Resonance** in this encyclopedia.

2.2.2 Dipolar Dephasing

The technique of dipolar dephasing (DD) is a variation of CP. In this case, the ^{1}H decoupler is switched off for a short time after the CP contact time. During this off-time, signals from different carbon types dephase at different rates, depending on the strength of the $^{1}H-^{13}C$ dipolar interactions. The characteristic time for this dephasing is T_2, the spin–spin relaxation time. Carbons that are directly attached to hydrogen (primary, secondary, and tertiary carbons) experience strong $^{1}H-^{13}C$ interactions and dephase more rapidly (~20 μs) than carbons without attached hydrogen (quaternary carbons) (50–100 μs). After about 50 μs the decoupler is switched on again and the observed signal is due primarily to quaternary carbons. However, because of their rapid rotation in the solid state, the signals from methyl groups (CH_3) do not completely dephase and are observed as part of the aliphatic carbon signal. These methyl carbons can be distinguished from the other quaternary aliphatic carbons on the basis of chemical shifts. Thus DD is a technique that discriminates between protonated and nonprotonated aliphatic and aromatic carbons. This information can be useful in deriving average molecular structures for insoluble solid materials such as kerogen and asphaltenes.

2.2.3 Single-pulse Excitation

The most fundamental and most quantitative NMR measurement is made using single-pulse excitation (SPE), sometimes referred to as Bloch decay. For ^{13}C NMR measurements in solids, SPE measurements are made in conjunction with high-power decoupling to minimize broadening caused by the $^{1}H-^{13}C$ dipole–dipole interaction and with MAS to eliminate broadening caused by the chemical shift anisotropy. SPE can be employed as an independent check of the quantitative reliability of CP/MAS aromaticity measurements.[23,24] The signals from SPE arise from relaxation mechanisms that are different from those in the CP experiment. Therefore, agreement between carbon aromaticities from the two measurements indicates that both measurements are observing the same types and amounts of carbon. However, in solids, ^{13}C spin lattice relaxation times can be on the order of minutes, necessitating long acquisition times to record an NMR spectrum. For example, a typical SPE/DD experiment employing 10 delays, 1000 scans, and a 20-s pulse delay takes 56 h.[24] Thus, the advantage of having quantitative data is partially offset by longer signal accumulation times to obtain a spectrum with a reasonably good S/N. The use of a large-volume sample spinner can negate much of this disadvantage because less time is required to obtain a good S/N.[9] Although NMR spectroscopists realize that there has been an improvement in quantitation

Figure 1 CP/MAS ^{13}C NMR spectrum of sub-bituminous coals, illustrating resolution typical of solid-state NMR.

using SPE methods, CP/MAS still is used more frequently because of the considerable saving in time.

2.3 Applications

2.3.1 Typical Nuclear Magnetic Resonance Spectrum of Carbonaceous Solid

A CP/MAS ^{13}C NMR spectrum of a carbonaceous solid is shown in Figure 1. The spectrum is that of a sub-bituminous coal. It illustrates the resolution typically obtained by CP/MAS NMR for these types of material, provided they have a sufficiently high percentage of total organic carbon (TOC) to give a good S/N in a reasonable amount of time (e.g. 1 h). The positions of different carbon types are shown on the spectrum. A listing of chemical shifts for the most common carbon functional groups is given in Table 1.[25] There is little resolution in the aliphatic carbon region (0–60 ppm), except for shoulders on the methylene band caused by methyl groups on aromatic rings and terminal methyl groups on long-chain paraffins. The aromatic carbon region shows more resolution from alkyl substituents, phenolic carbons, and carbonyl functionality. The main structural parameter obtained by CP/MAS is a measurement of the carbon aromaticity, i.e. the fraction of total carbon that is in aromatic (sp^2) carbon structures. Contributions from carbonyl carbons are often included in aromaticity measurements if the integrated signal intensity for the carbonyl carbons (165–210 ppm) is small. The spectrum was obtained at a spinning rate of 4.5 kHz, so spinning sidebands at 300 and −50 ppm are negligible. A petroleum source rock having a low TOC (<5%) would give a noisier signal and the shoulders, although present on the aliphatic and aromatic bands, would be more difficult to observe.

2.3.2 Natural Maturation with Depth of Burial

Thermal evolution of source rocks during natural maturation as a result of burial, or during artificial maturation as in pyrolysis, changes many of the physical and chemical properties of the organic matter (kerogen) in sedimentary rocks.[26,27] A depiction of thermal degradation of a hypothetical kerogen molecule is shown in Figure 2. In this example, temperature increases from top to bottom. The example shows the types of chemical change that are expected to occur during hydrocarbon generation resulting from burial for periods of geological time, or from elevated temperatures over short periods of time in the laboratory. In either situation, the thermal alteration of kerogen involves hydrogen disproportionation reactions in which the kerogen loses hydrogen to form liquid hydrocarbons, wet gas and dry gas in succession. The remaining hydrogen-deficient kerogen condenses to form larger aromatic clusters which would eventually form graphite.

The main chemical change depicted in Figure 2 is the progressive decrease in H/C (atomic hydrogen to carbon) ratio (increase in the carbon aromaticity) of the kerogen with increasing maturation. This change is brought about by aromatization of aliphatic carbons in hydroaromatic structures (tetralin type) and by cyclization and dehydrogenation of alkyl substituents. In addition, the number of

Table 1 List of carbon functionality used in peak identification of a ^{13}C NMR spectrum

Functionality	Structure	Symbol	ppm

side chains on the aromatic ring system decreases with maturation. The products of the reactions progressively become lower in molecular weight, with methane, CH_4, being the ultimate product. For simplicity, only hydrocarbon structures are shown; however, similar changes would be expected to occur with heteroatoms (N, S, O) in the ring system.

2.3.3 Changes in Nuclear Magnetic Resonance Spectra with Depth of Burial

NMR measurements provide important information on the catagenesis and maturation of the organic matter in sedimentary rocks. The chemical changes depicted in Figure 2 are observed as changes in the NMR spectra of sedimentary organic matter as a function of burial depth or temperature. Most NMR measurements show how the distribution of aliphatic and aromatic carbon changes with time and temperature during burial. CP/MAS ^{13}C NMR spectra for a suite of samples from the Wind River Basin in Wyoming representing different depths of burial are shown in Figure 3. The NMR spectra exhibit features that clearly support the types of chemical reaction in the scheme depicted in Figure 2. The spectra show an increase in the aromatic carbon fraction relative to the aliphatic carbon fraction with increasing depth (i.e. temperature). Aliphatic carbon structures are hydrogen rich and are largely responsible for the hydrocarbons that

Figure 3 CP/MAS ^{13}C NMR spectra of samples from the Wind River Basin, Wyoming, taken from different burial depths.

are generated during natural and artificial maturation. The increase in carbon aromaticity with depth is due to loss of aliphatic carbons to hydrocarbon generation and to aromatization reactions. However, it is not possible to partition these losses between the two types of reaction without detailed material balances and elemental analyses. Nevertheless, by monitoring the aliphatic and aromatic carbons as a function of burial depth, limits can be placed on the capacity of source rocks to generate hydrocarbons at depth. Such information is difficult, if not impossible, to obtain by other methods. The NMR spectra in this example suggest that in the Wind River Basin, most of the volatile products (oil and gas) are generated down to a depth of about 3570 m. At greater depths there is not a sufficient fraction of aliphatic carbons remaining to generate hydrocarbons.

The aliphatic carbon region (0–90 ppm) shows partial resolution of at least two types of carbon (see Figure 1). These can be assigned to methylene carbons (CH_2) in long chains (30 ppm), and methyl groups (CH_3) attached to aromatic rings (ca. 20 ppm). Methylene carbons in branched and cyclic aliphatic structures are also counted with the methylene carbons at 30 ppm. The resolution is more noticeable in the spectrum of the sample at 3415 m. At greater burial depths, the spectra show a shift in position of the maximum of the aliphatic carbon resonance from 30 ppm for methylene carbons in long chains to that of the methyl groups attached to aromatic rings at ca. 20 ppm. Ultimately, these methyl groups would be the source of methane gas at very high maturity (Figure 2). Resonances at 300 and −50 ppm, most clearly seen in the 6041 m spectrum, are spinning sidebands.

There is a narrowing of the width of the aromatic resonance band (90–200 ppm) with increasing burial depth. This narrowing is indicative of an increase in the number of fused rings in the polynuclear aromatic moiety and of a lesser amount of substitution on the aromatic rings as alkyl side chains are cleaved during oil and gas generation. During maturation, cleavage of substituents bridging aromatic rings also initiate condensation reactions that yield larger aromatic cluster sizes. Aromatization of aliphatic carbons to produce larger more condensed aromatic ring structures would limit the number of substituents per aromatic carbon in the ring. The net effect of all these changes is to narrow the chemical shift dispersion, which results in a narrower aromatic resonance band. The general features of the NMR spectra as a function of burial depth in Figure 3 have been observed for maturation of petroleum source rocks[28] and coals during hydrous pyrolysis.[29]

The CP/MAS ^{13}C NMR spectra also show a resonance band at ca. 180 ppm for the outcrop sample. This band is attributed to carboxylate carbon functionality. During maturation, decarboxylation reactions occur liberating CO_2. The CP/MAS ^{13}C NMR spectra in Figure 3 show that this carbon functionality has disappeared by the time that a depth of 2166 m is reached, illustrating that evolution of CO_2 occurs in the early stages of maturation.

During artificial maturation (pyrolysis), rapid evolution of CO_2 is observed at low temperatures and is thought to be a major contributor to crosslinking and retrograde reactions.[30]

2.3.4 Nuclear Magnetic Resonance Evaluation of Source Rock Potential

The changes that are observed in the NMR spectra of source rocks as a function of burial depth are also observed in the laboratory when the sample is heated to a high temperature for short periods of time.[29,31] As a result, an NMR spectrum can be used to evaluate a rock for its potential to produce liquid hydrocarbons during burial. An example is shown in Figure 4 for the case of an oil shale from Colorado and a sub-bituminous coal from Wyoming. The conversion data were obtained from a Fischer assay of the materials (see **Oil Shale and Shale Oil Analysis**).

The most important factor controlling the generation of oil and gas is the hydrogen content of the organic matter. The Colorado oil shale is from a lacustrine depositional environment and has a highly aliphatic carbon structure; therefore, it has a high hydrogen content. It would be an excellent petroleum source rock, given the property relating to the geological conditions of burial depth and time. The Wyoming sub-bituminous coal is of a terrestrial origin. It has a more aromatic carbon content and therefore is hydrogen deficient relative to the Colorado oil shale. These characteristics are shown in the NMR spectra and they correlate well with the conversion data.

Figure 4 CP/MAS ^{13}C NMR spectra of a Colorado oil shale and a Wyoming sub-bituminous coal, illustrating the effect of carbon structure on conversion to oil.

3 LIQUID-STATE NUCLEAR MAGNETIC RESONANCE CHARACTERIZATION OF PETROLEUM DISTILLATE FRACTIONS

Liquid-state NMR is unsurpassed as a spectroscopic technique for characterizing and quantifying the molecular structure and dynamics of monomolecular materials. In the study of complex materials such as petroleum, the technique is most often used for characterization and quantification of the structure of the various petroleum distillate fractions, including residues. ^{1}H and ^{13}C NMR have been used to study naphtha and gasoline,[32–34] middle distillates,[35,36] jet and diesel fuels,[37–41] light gas oil,[42] heavy oils,[43–45] light crudes,[46] waxes,[47] and residue and heavy ends, including asphaltenes and asphalts.[48–53] Most of the studies involved the use of one-dimensional NMR spectral techniques. However, studies have included the use of two-dimensional (2D) NMR spectroscopic techniques, which facilitate the spectral interpretation of complex mixtures. Compared to gas chromatography and mass spectrometry, a major advantage of NMR spectroscopy is that the technique can also be applied to fractions that have boiling points greater than 550 °C.

3.1 Experimental Procedures and Instrumentation

Petroleum crudes are complex solutions of thousands of different paraffinic, aromatic and heteroaromatic molecules. Neither NMR nor other spectroscopic techniques directly provide enough information fully to delineate the individual components present in the whole crudes. Thus, as with other techniques, fractionation of the crude oil is desirable to reduce the complexity of molecular types in a sample and to obtain meaningful information about the molecular structure from an NMR spectrum. The first fractionation is usually distillation, which yields products of the petroleum crude such as gasoline, kerosene and vacuum gas oils. The distillate products are listed in Table 2. The light distillates can also be easily characterized and quantified by mass spectrometry, other spectroscopic techniques such as infrared, and chromatographic methods. The light as well as heavy distillates can be separated further into saturates, olefins and aromatic structural groups, using solvent extraction and various

Table 2 Common distillation fractions of petroleum

Fraction	Boiling (°C)
Light naphtha	−1–150
Heavy naphtha	150–205
Gasoline	−1–180
Kerosine	205–260
Fuel oil	205–290
Light gas oil	260–315
Heavy gas oil	315–425
Lubricating oil	>400
Vacuum gas oil	425–600
Residuum	>600

chromatographic techniques. Because individual compounds cannot be easily identified in the fractionated samples, recourse must be made to approximate (average) structural characterization methods using information obtained from NMR, elemental and average molecular weight (AMW) data.

Petroleum fractions for NMR studies are usually dissolved in $CDCl_3$ containing a small amount of tetramethylsilane (TMS) as an internal reference for both ^1H and ^{13}C chemical shift measurements. Because of the high sensitivity of present-day NMR spectrometers, only a few milligrams of sample are needed for a ^1H spectrum and approximately 100 mg for a ^{13}C spectrum. To obtain quantitative data from a ^{13}C NMR spectrum, it is often necessary to add a small amount of the relaxation reagent, chromium(III) acetylacetonate, to a $CDCl_3$ solution of a distillate fraction.

Almost all experiments are performed using a Fourier transform NMR spectrometer at frequencies ranging from 100 to 400 MHz for ^1H and from 25 to 100 MHz for ^{13}C. Many of the spectrometers manufactured today are multinuclear, almost fully automated and computer controlled. In addition, many can be programmed to conduct two- and three-dimensional spectral data acquisition.

3.2 One-dimensional Nuclear Magnetic Resonance

3.2.1 ^1H Nuclear Magnetic Resonance

The hydrogen (^1H) resonance signal is the most easily detected signal of any of the elements, and the area of the ^1H resonance quantitatively represents the number of hydrogens of a given type within a molecule. Two disadvantages of the ^1H NMR technique for investigation of complex mixtures are the spin–spin scalar coupling of adjacent hydrogens in a molecule and the small chemical shift range for the different hydrogen types (0–15 ppm). The scalar coupling results in splitting of a given hydrogen type into multiple peaks. The splitting pattern (multiplicity) is useful diagnostically for determining the structural groups adjacent to one another in molecules. However, in complex mixtures of molecules the splitting patterns of the various hydrogens overlap one another, resulting in the loss of resolution and information related to the coupling of adjacent hydrogen groups. This loss of resolution, together with chemical dispersion (many hydrogen types in the different compounds with similar but not equal chemical shifts), results in a broad envelope of resonances for the methyl, methylene, methine, olefinic and aromatic hydrogen types.

Figures 5 and 6 show the 400 MHz ^1H spectra of a regular grade gasoline and of an asphalt, respectively. The high resolution of the resonances peaks observed for the ^1H spectrum of the gasoline relative to asphalt is due to the relatively low molecular weight and lower number of compounds found in gasoline. The peak at 0 ppm is the chemical shift reference, TMS. The peak at 7.24 ppm results from a small residue of $CHCl_3$ in $CDCl_3$. The spectra shown in Figure 5 can be divided into three major hydrogen types: aliphatic, olefinic, and aromatic. The aliphatic hydrogens have chemical shift values ranging from 0.5 to 4.0 ppm. This region can be further divided into resonances associated with the methyl, methylene and methine functional groups. The chemical shift range from 4.0 to 6.0 ppm represents the resonances due to olefinic hydrogens. The resonance profile in this region can be used to determine the types of olefin present.[54] The aromatic hydrogens lie in the chemical shift range from 6.6 to 8.3 ppm, which can be divided further into hydrogens associated with mono-, di-, and tri-aromatic ring systems. The ^1H chemical shift ranges for the various

Figure 5 400 MHz ^1H NMR spectrum of a regular grade gasoline.

Figure 6 400 MHz ^{1}H NMR spectrum of an asphalt.

hydrogen types in hydrocarbons are given in Table 3. The interpretation of the ^{1}H spectrum is further complicated if there are significant concentrations of aliphatic groups adjacent to heteroatomic groups containing nitrogen, oxygen and sulfur. Thus, before attempting to assign the peak in a ^{1}H spectrum, some knowledge of elemental and functional group composition is desirable. Conclusions can be drawn from ^{1}H NMR data about the average carbon skeleton if one assumes a definite H/C ratio for the aliphatic constituents. However, the combined use of ^{13}C and ^{1}H NMR data is the preferred method.

Table 3 ^{1}H and ^{13}C NMR chemical shift ranges

Definitions	Chemical shift range (ppm from TMS)
^{1}H	
Monoaromatic hydrogens	6.6–7.2
Diaromatic hydrogens	7.2–7.8
Triaromatic hydrogens	7.8–8.3
Olefinic hydrogens	4.0–6.0
Methylene hydrogens alpha to aromatic ring	2.3–4.0
Methyl hydrogens alpha to aromatic ring	1.9–2.3
Naphthenic hydrogens beta to aromatic ring	1.6–1.9
β-CH_2– and β-CH_3 to aromatic ring and straight chain alkane methylene hydrogens	1.0–1.6
γ-CH_3 to aromatic ring and straight chain or branch alkane methyl hydrogens	0.5–1.0
^{13}C	
Total aromatic/olefinic carbons	100–150
Total aliphatic carbons	5–50
Methyl carbons of straight chain alkanes	13.8–14.2
C_2-Methylene carbons of straight chain alkanes	22.7–23.0
C_3-Methylene carbons of straight chain alkanes	31.8–32.0
$C_{4,5,n}$-Methylene carbons of straight chain alkanes	29–30

Several instrumental parameters must be established for reliable quantification of the NMR integration data. Typically, long relaxation delay times between 5 and 20 s, with a relatively small pulse angle (<40°), are used to acquire ^{1}H Fourier transform (FT) spectra. Good integration of the data can easily be obtained, but depends on having correct phasing and a flat baseline. Absolute determination of the hydrogen content by NMR is not often performed, but can be accomplished by adding an accurately weighed pure compound with a single ^{1}H resonance peak to the sample of interest.[55,56] The chemical shift of this reference compound must be in a region which does not interfere with the integration of the hydrogens associated with the sample.

Relative integration values from a ^{1}H spectrum are typically obtained for the different hydrogen types. Because the resonance signals for the total aromatic and aliphatic hydrogen types are widely separated, reasonably good accuracy and precision of the integration can be achieved. However, within the aromatic and aliphatic hydrogen regions, where only partial separation of hydrogen types are observed, the integration of the hydrogen types is less accurate and depends on the chemical shift range assigned to the particular hydrogen type. High field spectra for some samples can increase the resolution between hydrogen types and thus provide better integration values. 2D NMR spectra can also provide good resolution in some cases, but accurate integration can be more difficult.

3.2.2 ^{13}C Nuclear Magnetic Resonance

The natural abundance of the carbon-13 isotope is 1.1%. However, with the advent of Fourier transform NMR, this isotope of carbon is easy to detect and in most cases is the element of choice for investigation of fossil fuel materials. Unlike hydrogen, the scalar coupling between carbon and hydrogen nuclei can be decoupled electronically using a broad-band amplifier. Thus, a single resonance for each different carbon within a molecule is observed, resulting in greater resolution between carbon types. In addition, the chemical shift range (0–220 ppm) is much greater than for hydrogen. The large shift range reduces the extent of overlapping resonances and facilitates carbon-type identification. Unfortunately, chemical dispersion is also a major contributor to the broad resonances observed in carbon spectra of complex mixtures.

Figure 7 100 MHz ^{13}C NMR spectrum of a regular grade gasoline.

Figure 8 100 MHz ^{13}C spectrum of an asphalt.

^{13}C spectra of a regular grade gasoline and an asphalt are shown in Figures 7 and 8. Because there are fewer compounds, a large ^{13}C chemical shift range and broadband decoupling of the hydrogens, the resonance peaks, which each represent a single carbon type, are well resolved for the gasoline compared to those for the asphalt spectrum. The lower resolution and broader peaks in the asphalt are the result of chemical shift dispersion caused by the many compounds and shorter relaxation times for the carbon atoms. The ^{13}C spectrum of a hydrocarbon has two distinct chemical shift regions. The chemical shift for the aliphatic carbon-types ranges from 5 to 50 ppm and the aromatic carbons range from 100 to 150 ppm. Carbons adjacent to heteroatoms (nitrogen and oxygen) are often resolved in many light petroleum distillates. Phenolic and carbonyl carbons have chemical shifts ranging from 150 to 210 ppm, oxygenated aliphatic carbons have a range of 40 to 60 ppm. The three peaks in each spectrum centered at 78 ppm are due to the carbon atom coupled to the deuterium atom of the solvent $CDCl_3$. The olefinic carbons, if present, would have chemical shift values which overlap the aromatic carbon chemical shift range and are not easily identified in a one-dimensional NMR spectrum. In this case, the ^{1}H spectrum is preferred for identification and quantification of olefins. However, with advanced techniques such as 2D C–H correlation experiments, olefinic carbons can be identified and quantified (see section 3.3). Depending upon the petroleum distillate and subfractions of the distillates, the aromatic and aliphatic region can be further subdivided into different carbon types using various spectral editing and 2D NMR techniques (see sections 3.2.3, 3.3, and 3.7.2). These methods can be used to resolve tertiary and quaternary aromatic carbons and the methyl, methylene, methine, quaternary aliphatic carbons. In the asphalt spectrum (Figure 8) only the methyl (14 ppm) and methylene carbons (23, 30 and 32 ppm) of straight chain alkanes are readily identifiable. Table 3 lists the carbon-13 chemical shift for various carbon types in hydrocarbons.

The nuclear parameters which affect the quantitation of the carbon resonance signals are the ^{13}C spin–lattice relaxation time and the nuclear Overhauser enhancement effect (NOE). Carbon relaxation times are considerably longer than for hydrogens. In addition, aromatic quaternary carbons (bridgehead or from alkyl-substituent) in a molecule have much longer relaxation times relative to other carbons with attached hydrogens. To shorten and equalize the relaxation times among the various carbons, a relaxation reagent is often added to the sample. The most often used relaxation reagent is chromium(III) acetylacetonate at a concentration of about 0.05 M. Even with this reagent, instrumental parameters such as a small pulse angle of $<90^{\circ}$ and a pulse sequence delay of 5–10 s are used. The NOE on the various carbons can differ significantly but can be reduced using an inverse gated decoupling pulse sequence. This pulse sequence minimizes the NOE of all carbon signals, but because the signal enhancement by this effect is lost, time averaging processes must be increased to achieve a good S/N ratio. As with ^{1}H NMR, reliable integration of a carbon spectrum depends on correct phasing and a flat baseline.

3.2.3 Spectral Editing

NMR spectra of petroleum distillates are often recorded with the objective of elucidating the molecular structural characteristics of the sample in an effort to understand better its physicochemical properties and to monitor changes in process conditions. The usual approach involves subdividing the conventional ^{1}H and ^{13}C NMR spectra into chemical shift regions, each of which is

assumed to be associated with a single type of hydrogen or carbon substructure. If suitable experimental precautions are taken, integration yields the relative abundance of the different ^{1}H and ^{13}C aromatic and aliphatic structural types. However, chemical shift–structure relationships are limited in scope because of the ambiguities associated with determining the chemical shift range for many different hydrogen and carbon types in a fossil fuel. It is difficult to know where to subdivide spectra in such a way that structural inferences are both detailed and valid. Too large or too small a range will increase or decrease the relative abundance of the different structural types and increase the uncertainty of structural inferences. In addition, structural information such as the hydrogen connectivity and carbon multiplicity of the structural groups is lost when using conventional ^{1}H and ^{13}C experimental techniques for complex mixtures.

An alternative approach to quantify the NMR spectral data of any petroleum fraction into carbon types (CH_n, $n = 0–3$) is to use spectral editing techniques, i.e. separation of ^{13}C spectra into methyl (CH_3), methylene (CH_2), methine (CH), and nonprotonated or quaternary (C) carbons. The distortionless enhancement by polarization transfer (DEPT),[37,57–60] quaternary only carbon spectrum (QUAT),[61] gated spin-echo ^{13}C NMR (GASPE)[62,63] and the spin-echo broad-band off-resonance decoupling (SEBBORD)[64,65] are a few of the techniques that have been developed to regain the carbon multiplicity information and to define more precisely the chemical shift range for different carbon types in a complex molecule or mixture of molecules. These methods are based upon obtaining a series of spectra by modulating the signal intensities of the CH_n group as a function of either the ^{1}H pulse width, θ (DEPT) or the $^{13}C–^{1}H$ scalar spin-coupling characterized by a spin-coupling constant, J_{CH} (GASPE). A linear combination of these spectra results in edited spectra of the specific carbon types (DEPT CH_n, $n = 1–3$ and GASPE CH_n, $n = 0–3$). Figure 9 shows the conventional ^{13}C spectrum and the ^{13}C edited DEPT spectra for the various carbon types in the saturate fraction obtained from the 200–425 °C distillate cut from the Cerro Negro heavy petroleum. Also shown is the quaternary only (QUAT) ^{13}C spectrum. The spectra shown can be integrated to give the relative fractional amounts of the various carbon types. From a knowledge of the fractional amounts of carbon types, a number of average molecular structural parameters can be determined (see section 3.4).

3.3 Two-dimensional Nuclear Magnetic Resonance

In spectra which are inherently crowded, such as those of complex mixtures of different hydrocarbons, overlapping resonances of the various carbon types can often be separated and/or identified by introducing an additional dimension to the normal intensity versus chemical shift (frequency) representation of an NMR spectrum. The introduction of a second frequency dimension can be either a second chemical shift or a scalar-coupling parameter. The application of 2D NMR techniques to fossil fuels is relatively new, but their value is becoming increasingly apparent.[66,67] The application of 2D NMR to the complex mixtures of chemical types encountered in such fossil fuel liquids as shale oils, coal liquids, or petroleum have been reported.[68–72] The application of

2D methods to fossil fuels has been limited to oils and distillates, since heavier fractions, such as asphaltenes, usually do not give sufficient resolution even at high field.

In principle, two classes of 2D experiments exist: *J*-resolved (2D-*J*) and correlated 2D spectra. The first is characterized by one frequency axis containing the coupling (multiplicity) information and by another frequency axis containing the chemical shifts. In a second type, both frequency axes contain chemical shift information. The connection between the two frequency axes is through scalar coupling (homonuclear [^{1}H–^{1}H] as well as heteronuclear [^{1}H–^{13}C]) or through dipolar coupling.

Figure 10 shows a homonuclear (^{1}H–^{1}H) 2D-*J* spectrum[70] of an aromatic petroleum solvent (PETSOL), which mainly consists of a mixture of alkyl benzenes. The *x*-axis represents the ^{1}H chemical shift of the alkyl hydrogens, the *y*-axis the coupling (multiplicity) information, and the *z*-axis the intensity. The multiplicity reflected in the (^{1}H–^{1}H) coupling gives information on neighboring ^{1}H group interactions. Peak 7 shows that the methyl hydrogens are split into a triplet, which indicates the methyl group is adjacent to a group containing two hydrogens (the adjacent methylene group in the alkyl substituent). The three-dimensional presentation of the data can also be done in the form of a contour plot,[70] as shown in Figure 11.

Homonuclear correlated 2D NMR data from a correlation spectroscopy (COSY)-90 experiment[72] are presented in Figure 12 for a monoaromatic diesel fraction. The contour format is employed. Both horizontal and vertical axes pertain to the ^{1}H chemical shift. All ^{1}H groups

Figure 10 ^{1}H 2D NMR *J*-spectrum of PETSOL. ^{1}H chemical shift (ppm) on the *x*-axis. ^{1}H coupling (Hz) on the *y*-axis. The one-dimensional (1D) ^{1}H NMR spectrum is shown at the top of the diagram. (Reproduced by permission of Elsevier Science from D.J. Cookson, B.E. contribute to intensity on the diagonal. Off-diagonal peak intensity arises when two ^{1}H groups of different chemical shifts are coupled. The relationship between regions in the ^{1}H NMR spectrum can be interpreted as follows:[72] peaks 1 and 20 are coupled and belong to the 1-methylindan ring: 2–19, isopropyl; 3–9, indan ring: 4–17, 1-methyltetralin ring: 5–11, tetralin ring; 7-(13/12)-23, propyl; 7-(13/14)-(15/16)-22, butyl; 8,α $-OH_3$ not coupled, and 10–21, 2-methyltetralin ring.

The 2D heteronuclear (^{1}H–^{13}C) correlation (HETCOR) spectrum[71] of an aromatic fraction separated from a high-speed diesel fuel sample is shown in Figure 13. The 2.0–3.5 ppm region of the ^{1}H NMR spectrum is shown along the vertical axis, whereas the horizontal axis shows the ^{13}C DEPT 135° spectrum of the carbons in the aliphatic region (5–50 ppm). In the DEPT spectrum, signals of the CH and CH_3 carbons appear as negative and those from CH_2 appear as positive peaks. The signals between 18 and 20 ppm in the ^{13}C NMR spectrum are due to the methyl substituents of the aromatic carbons. These signals are used to assign the ^{1}H NMR region from 2.0 to 3.5 ppm to the hydrogens of the methyl group attached to an aromatic ring. Upon closer examination of the HETCOR spectrum, the ^{1}H region between 2.4 and

Figure 12 $^{1}H-^{1}H$ Homonuclear COSY 2D NMR spectrum of the aliphatic H_n groups in a fossil fuel diesel (monoaromatic fraction). Srivastava, A.K. Bhatnagan, *Energy Fuels*, **12**, 1223–1227 (1998).[71] Copyright (1998) American Chemical Society.)

3.5 ppm contains signals due to both α-CH_2 and α-CH_3 substituents on the aromatics.

A stacked plot of the HETCOR experiment[69] performed on a fossil fuel liquid containing both aromatic and olefinic material is shown in Figure 14. The 1D-^{13}C spectrum (vertical axis) shows complete overlap of the two types of sp^2 carbons. The 1D-^{1}H spectrum (horizontal axis), however, gives complete separation of the aromatic and olefinic hydrogens. Thus, through the use of the 2D/HETCOR spectrum, the olefinic ^{13}C peaks can be assigned based upon the splitting pattern observed in the ^{1}H spectrum. Several of the ^{13}C peaks are identified as specific types of olefin (shown in Figure 14). The unlabeled peaks are unassigned protonated aromatic carbons.

The preceding illustrations of the spectral editing and 2D NMR methods represent a few of the many techniques that are available to the NMR spectroscopist in an effort to identify and quantify carbon types in complex materials.

3.4 Average Molecular Structural Parameters

Detailed compositional characterization of petroleum fractions is extremely important, but has proved to be quite difficult and time-consuming. For these reasons, procedures have been reported which describe a particular fraction in terms of a hypothetical molecule.[73–75] The methods of average molecular structural determination usually incorporate results of elemental analysis, ^{1}H and ^{13}C NMR spectroscopy, and average molecular weight (AMW) determination from vapor pressure osmometry (VPO) to define the structural parameters of an average

molecule. Table 4 lists some of the average parameters which are generally determined for petroleum fractions. It is important to realize that these average parameters are weighted averages for certain properties of the sample and may not represent actual structures present in the petroleum fraction. There is little evidence to indicate that complex mixtures exhibit the chemical and physical behaviors predicted by a single hypothetical structure. However, it can be reasoned that the narrower the distillation cut, the more the ''average molecule'' represents the chemical and physical properties of the fractions. There are many hidden assumptions in calculating the average molecular structure of a petroleum fraction.[76,77] One important major assumption is that all alkyl groups are present as substituents on aromatic rings. In solid materials, this is probably a good assumption (see section 4.1).

3.5 Applications

3.5.1 Average Molecular Weight

Characterization of oil fractions using average molecular parameters obtained by quantitative NMR analysis is often used to monitor the changes in composition at various stages of conversion processes and for simulating thermophysical properties of crude oil, such as phase equilibria. To simulate the thermophysical properties of crude oil, accurate values for the AMW of the oil distillate fractions are required to establish a relevant equation of state for the fluid. The data obtained through VPO are sometimes questionable.[78]

NMR structural analysis models can be used to obtain AMWs of high-boiling aromatic fractions.[78] A model using a ^{13}C spectral editing technique has been found to be particularly reliable. Tests on 17 narrow high-boiling aromatic fractions of a North Sea crude oil gave very good agreement with mass spectrometry data. In another study, a simple algorithm based on data from NMR spectra gives AMW values consistent with VPO values for different fractions as distillates, residues or asphaltenes.[79]

3.5.2 Characterization of Chemical Class in Petroleum Distillates

Spectral editing techniques, DEPT and QUAT, have been used to characterize and quantify several saturate fractions from a Cerro Negro heavy petroleum crude.[37] Saturate hydrocarbon fractions have been obtained from the 200–425, 425–500 and 550–700 °C distillate cuts and the >700 °C residue. The average molecular structural parameters calculated from the NMR data are given in Table 5. Quantitative ^{13}C NMR subspectral analysis has provided detailed molecular structural information on saturate fractions that have atmospheric equivalent

Table 5 Average molecular structural parameters for the saturate fractions from the Cerro Negro heavy petroleum crude

Structural parameter	Saturate fraction			
	200–425 °C	425–550 °C	550–700 °C	>700 °C
H/C ratio	1.85	1.91	1.84	1.89

boiling points above the temperature for effective use of the GC/MS and ASTM (American Society for Testing and Materials) D-2786 mass spectral techniques. For the 200–425 and 425–550 °C distillate fractions, the NMR data correlate reasonably well with mass spectral data.

Conventional ^{13}C and ^{1}H NMR and spectral editing technique GASPE were used to provide detailed quantitative information regarding the abundance of major and minor alkanes and olefins in jet and diesel fuels from a Fischer–Tropsch syncrude.[80] The jet fuel consisted primarily of *n*-alkanes (87 wt%), while branched alkanes with, on the average, 12 carbon atoms per molecule and one CH_3 branch per molecule, represent another 9 wt%. Olefins represent nearly 4 wt% of the sample. From ^{1}H and ^{13}C NMR spectra of the olefins, the *cis* and *trans* isomers, as well as the position of the double bond, could be distinguished. Similar results were found for the diesel fuel in which the average number of carbon types per molecule was found to be approximately 15.

The branched and cyclic alkanes from the saturate fractions from diesel and kerosene fuels were characterized using the ^{13}C NMR technique, GASPE, to determine the fractional abundance of CH_n groups.[81,82] The *n*-alkane and branched plus cyclic alkanes were separated from each other using silica chromatography and urea clathration. The NMR data were used in calculating several average structure parameters, which included: number of branches per molecule, number of branches per branched molecule, number of branches per cyclic molecule, and number of rings per cyclic molecule.

A direct and fast method for estimating the aromatic carbon content in hydrofinished and hydrotreated types of base oils using ^{1}H NMR spectroscopy was reported by Sarpel et al.[83] In developing the method, the 2D HETCOR spectral analysis technique was used, which facilitated the estimation of quaternary and bridgehead aromatic carbons from the ^{1}H NMR spectrum. Using derived equations, the complete assignment of the ^{1}H NMR spectrum can be made, from which the aromatic content can be determined for the base oils. The methodology is highly useful for routine quality control analysis where a large number of base oils are required to be analyzed in a limited time. In principle, the method should easily be extended to other heavier ends like vacuum gas oils.

Bansal et al.[71] reported the methodology for the estimation of total aromatics and their distribution as mono- and polynuclear aromatics in diesel-range fuel products. The method is also based on the detailed analysis of the ^{1}H NMR spectrum. Advanced NMR techniques such as DEPT and 2D HETCOR were applied for the unambiguous assignment of the α-substitution on the aromatic ring in the ^{1}H NMR spectra (2.0–3.5 ppm region). The proposed ^{1}H NMR-based method correlates very well with the standard HPLC(IP-391/90) and mass spectrometric-based techniques.

1D and 2D NMR methods can be used to elucidate the structural characteristics of the monoaromatic fractions from petroleum and synthetic fuels.[72] Spectral assignments are supported by a range of NMR information, including CH_n types ($n = 0$–3), ^{1}H and ^{13}C chemical shifts, $^{1}H-^{13}C$ and $^{1}H-^{1}H$ resonance connectivities, and ^{1}H multiplicity. From the information provided by the various NMR techniques, the average number of α-CH_3, β-CH_3, γ-CH_3 groups per molecule can be calculated and a range of specific structures can be identified. Overall, the structural data are sufficient to identify similarities and differences for the monoaromatic fractions from different Australian petroleum sources.

3.5.3 Gasoline Octane Number

The octane number of a gasoline is a function of its chemical composition and therefore should correlate with the hydrocarbon types present. Mühl et al.[32] reported a correlation between the reformed gasoline chemical composition and its research octane number (RON) determined by the standard ASTM method (D2699). Using ^{1}H NMR spectral data to quantify the various hydrocarbon hydrogen types in 62 gasoline samples, they obtain the following linear regression relationship, Equation (1)

$$\text{RON (NMR)} = 92.37 + 0.30H_A + 0.31H_B - 0.87H_C - 0.35H_D \quad (1)$$

where H_A is the percentage of aromatic ring hydrogens, H_B is the percentage of α-aromatic CH_3 hydrogens, H_C is the percentage of paraffinic CH hydrogens, H_D is the percentage of paraffinic CH_2 hydrogens.

The method gives a satisfactory level of accuracy and is suitable for determining the octane number of gasoline samples generated in the laboratory when small sample quantity prevents use of the standard method.

3.5.4 Diesel Cetane Number

The cetane number (CN) measures the ignition quality of a diesel fuel. The effect of hydrocarbon type composition of the fuel on the ignition quality is qualitatively well-known. However, analytical methods to identify the amount of each hydrocarbon are time-consuming and thus prevent the establishment of models to represent quantitatively the effects of hydrocarbon type on ignition quality. Gülder and Glavincevski[84] developed a ^{1}H NMR method to predict the CN of diesel fuels from the carbon-type structural composition. Based on the carbon-type composition of 67 fuels, the CN can be predicted

using an expression of the functional form, Equation (2)

$$CN = B_0 + \frac{B_1}{C_A} + \frac{B_2}{C_A^2} + (B_3 C_\alpha + B_4 \ln C_\alpha) + (B_5 C_2 + B_6 C_2^2) + (B_7 C_3 + B_8 C_3^2) \quad (2)$$

where C_A is the number of aromatic carbons, C_α is the number of carbons at the α-position to aromatic rings, C_2 is the number of CH_2 CH carbons including β-CH_2, γ-CH_2 and β-CH_3 to aromatic rings, C_3 is the number of CH_3 carbons including terminal and branched and γ to aromatic rings, and $B_0 = 24.3848$; $B_1 = -286.728$; $B_2 = 587.3567$; $B_3 = 1.5227$; $B_4 = -15.882$; $B_5 = 0.9778$; $B_6 = 0.0047$; $B_7 = -0.2835$; $B_8 = 0.002$.

The constants, B_i, are determined by a multiple regression analysis fit of the data. The accuracy of the correlation is better than the accuracy of the cetane engine measurement on the basis of the spread of CNs determined by a number of standard cetane rating engines.

3.5.5 *Lubricant Base Oils*

Base oils are lubricant components which provide a fluid layer to separate dynamic surfaces. The fluid layer removes heat and wear particles while keeping friction at a minimum. The properties of base oils depend on the chemical composition and structural characteristics of hydrocarbon molecules present in the matrix. NMR techniques have been used to understand the carbon and hydrogen distribution in base oils in terms of average structural parameters (see Adhvaryu et al.[85] and the references they cite). These parameters, in principle, can be correlated with the basic properties required as specification for lube oil formulations. Using ^{13}C NMR, Singh et al.[86] studied industrial base oils refined from light and intermediate viscosity distillates and an aromatic-rich oil. A number of NMR average structural parameter values (Table 6) were correlated with several physicochemical characteristics of the lube base stocks (Table 7). Reasonable good correlations were determined for the percent aromatic carbon with the weight percent of sulfur, aniline point, the UOP characteristic factor, and the viscosity index. The study reveals that NMR could be

a potent technique for predicting various physicochemical properties which are used for base oil specifications (see also section 4.2).

4 SOME APPLICATIONS OF NUCLEAR MAGNETIC RESONANCE TO PETROLEUM PROCESSING

4.1 Average Molecular Structures Using Solid-state Nuclear Magnetic Resonance

The observed NMR signals represent all the carbons in the sample and cannot distinguish whether these carbons are in a single molecular entity or in a mixture of many different molecular types. Sometimes it is advantageous to construct an average molecule from average molecular structural parameters to monitor changes that result from varying process conditions, feedstocks, or other variables. In petroleum fractions, in which aliphatic and aromatic carbons, for example, exist in separate compounds, an average molecule does not represent the average properties of the mixture and is of little value in studying changes in process conditions. In solids such as coals, however, the situation is different because the concentration of paraffins is small. Any aliphatic carbons present are usually assumed to be attached to an aromatic cluster so that an average molecular representation can be constructed and the change in process conditions can be monitored.

Solum et al.[87] have devised an NMR procedure for calculating a number of molecular parameters that are useful in petroleum processing that involves solid or insoluble materials. DD relaxation data and integrated intensities of selected chemical shift ranges in a CP/MAS NMR spectrum are used to calculate 12 basic structural parameters, from which an additional eight structural parameters can be derived. A list of representative chemical shifts and carbon structures is given in Table 1. Definitions of the integrated areas are listed in Table 8. The superscripts on the areas refer to the chemical shift range in parts per million over which the integrals are evaluated. NMR structural parameters and additional lattice parameters derived from these data are given in Table 9. The procedure for calculating the structural parameters in Table 9 is from Solum et al.[87]

Storm et al.[88] used this procedure to develop molecular representations of petroleum asphaltenes and to develop correlations that predict fouling due to sludge formation in visbreaking and hydrocracking processes. Sludge formation occurs when asphaltenes flocculate. Therefore a better understanding of asphaltene molecular properties could lead to a better understanding of the mechanisms of coking and sludge formation in refinery operations. However, it should be stressed that asphaltenes are defined on the basis of solubility and that an asphaltene molecule per se does not exist. Asphaltenes are a mixture of strongly interacting molecules having colloidal properties. Therefore using an average asphaltene structure to represent a mixture is somewhat dubious and should be used with caution.

Nevertheless, Storm et al.[88] derived molecular representations of Ratawi and Alaska North Slope asphaltenes. These differed from other ''average structure'' calculations in that a molecular weight is not independently measured in order to calculate the average molecule. Instead the procedure automatically provides estimates of the AMWs that are consistent with independent determinations. The Ratawi asphaltenes are represented by four condensed rings with four side chains

Table 8 Definition and symbols for the measured and calculated parameters used in DD and CP NMR techniques

Parameter	Measured and calculated
Total intensity of aromatic carbons at dephasing time, t	$M(t) = M_G^0 \exp(-0.5(t/T_{2G})^2) + M_L^0 \exp(-t/T_{2L})$
Intensity of protonated aromatic carbons at $t = 0$	M_G^0
Intensity of nonprotonated aromatic carbons at $t = 0$	M_L^0
Gaussian component of DD relaxation time constant	T_{2G}
Lorentzian component of DD relaxation time constant	T_{2L}
Dephasing time	t
Aliphatic carbon integrated area from 0 to 90 ppm	A^{0-90}
Carbonyl carbon integrated area from 165 to 240 ppm	$A^{165-240}$
Aromatic and carbonyl carbon integrated area from 90 to 240 ppm	A^{90-240}
Phenolic carbon integrated area from 150 to 165 ppm	$A^{150-165}$
Alkyl substituted aromatic carbon integrated area from 135 to 150 ppm	$A^{135-150}$
Aromatic carbons integrated area from 90 to 165 ppm	A^{90-165}
Aliphatic carbons bonded to oxygen integrated area from 50 to 90 ppm	A^{50-90}
Methoxy carbon integrated area from 50 to 60 ppm	A^{50-60}
Methyl carbon integrated area from 0 to 25 ppm	A^{0-25}

Table 9 Calculation of structural and lattice parameters

Definition	Formula
Structural parameters	
1. Fraction of total sp^2 carbon (f_a)	$f_a = A^{90-240}/(A^{0-90} + A^{90-240})$
2. Fraction of total sp^3 carbon (f_{al})	$f_{al} = 1 - f_a$
3. Fraction of carbonyl carbons (f^{CO})	$f^{CO} = f_a(A^{165-240}/A^{90-240})$
4. Fraction of aromatic carbons (f'_a)	$f'_a = f_a - f^{CO}$
5. Fraction of phenolic carbons (f_a^P)	$f_a^P = f'_a(A^{150-165}/A^{90-165})$
6. Fraction of alkyl substituted aromatic carbons (f_a^S)	$f_a^S = f'_a(A^{135-150}/A^{90-165})$
7. Fraction of methyl and methoxy carbons (f_{al}^*)	$f_{al}^* = f_{al}\{(A^{0-25} + A^{50-60})/A^{0-90}\}$
8. Fraction of methine and methylene carbons (f_{al}^H)	$f_{al}^H = f_{al} - f_{al}^*$
9. Fraction of aliphatic carbons bonded to oxygen (f_{al}^O)	$f_{al}^O = f_{al}(A^{50-90}/A^{0-90})$
10. Fraction of quaternary aromatic carbons (f_a^Q)	$f_a^Q = M_L^0/(M_L^0 + M_G^0)$
11. Fraction of tertiary aromatic carbons (f_a^T)	$f_a^T = 1 - f_a^Q$
12. Fraction of protonated aromatic carbons normalized to total carbons (f_a^H)	$f_a^H = f'_a \times f_a^T$
13. Fraction of quaternary aromatic carbons normalized to total carbons (f_a^N)	$f_a^N = f'_a \times f_a^Q$
14. Fraction of aromatic bridgehead carbons (f_a^B)	$f_a^B = f_a^{Q'} - f_a^P - f_a^S$
Lattice parameters	
15. Mole fraction of bridgehead carbons (χ_b)	$\chi_b = f_a^B/f'_a$
16. Mole fraction of bridgehead carbons for linear catenation cluster ($\chi_{b'}$)	$\chi_{b'} = (1/2) - (3/C_{ar})$
17. Mole fraction of bridgehead carbons for circular catenation cluster ($\chi_{b''}$)	$\chi_{b''} = 1 - (6/C_{ar})^{1/2}$
18. Number of aromatic carbons per cluster (C_{ar})	$\chi_b = \{1 + \tanh[(C_{ar} - C_o)/m]\}\chi_{b'}/2 + \{1 + \tanh[(C_{ar} - C_o)/m]\}\chi_{b''}2$ $C_o = 19.57 \quad m = 4.15$
19. Number of attachments per cluster ($\sigma + 1$)	$\sigma + 1 = (f_a^S + f_a^P)C_{ar}/f'_a$
20. Fraction of intact bridges per lattice (P_o)	$P_o = (f_a^S + f_a^P - f_{al}^*)/f_a^S + f_a^P)$
21. Number of bridges and loops per cluster (BL)	$BL = (\sigma + 1)P_o$
22. Number of side chains per cluster (SC)	$SC = (\sigma + 1) - BL$
23. Molecular weight of cluster (MW_c)	$MW_c = (12C_{ar})/f'_a(\%C/100)$
24. Molecular weight per attachment	$M_\delta = [MW - (12f_a^N C_{ar} - 13f'_a)/(f_a^N + f_a^H)]/(\sigma + 1)$

and one connecting bridge, whereas the Alaska North slope asphaltenes are represented by four condensed rings with three side chains and one connecting bridge.

Sludge formation during heavy oil upgrading is a problem in many petroleum refinery processes. Often a soft coke-like substance forms during visbreaking and hydrocracking processes. This limits the severity of the conversion because it accumulates in downstream equipment, causing fouling. Because more petroleum operations use the bottom-of-the barrel for upgrading, methods to predict the production rate of sludge formation from chemical characteristics of the crude oil are of great importance. Storm et al.[89] found that the propensity of a feedstock to form sediment is related to a parameter which characterizes the degree of condensed polynuclear aromaticity of the resid. The polynuclear aromaticity is defined as the fraction of aromatic bridgehead carbons. This value can be obtained from NMR data using the formulas given in Table 9. The propensity to form sludge is higher the more the polynuclear aromatic hydrocarbon cores are highly substituted with alkyl groups. The degree of substitution can also be obtained from NMR data using the formulas in Table 9.

When applying the analytical procedure just described, it should be pointed out that, depending on the material under investigation, not all carbon types are necessarily present in the sample, and, therefore, will not be observed in the normal CP/MAS spectrum. For example, the procedure described was derived for characterization of coals. Phenolic and carboxylate carbon structures are generally part of the organic structure of these materials. In asphaltenes, these carbons are usually absent, or in low abundance and can be ignored.

4.2 Predictive Property Correlations

As the world continues to deplete its supply of high-quality crude oil, heavy crude oils that contain molecules of higher molecular weight and are more aromatic and contain more heteroatoms are being processed to a greater extent than previously. To process these heavy oils, their thermodynamic and transport properties must be known. Methods to estimate these basic parameters generally use normal boiling points and liquid densities at 15.6 °C (60 °F).[90] Many of these correlations are not applicable to fossil fuels that contain a significant number

of heteroatoms. In addition, the liquid densities and boiling points that are needed may be experimentally inaccessible.

NMR can be used effectively to provide molecular structure parameters for use in predictive property calculations.[91–94] Schwarz and Prausnitz[91] used NMR to develop a correlation for thermodynamic properties of heavy fossil-fuel fractions. Elemental analyses provide the relative abundances of C, H, O, N, and S atoms. An NMR spectrum is used to distinguish between: hydrogen bonded to an aromatic carbon, hydrogen bonded one carbon away from an aromatic ring, hydrogen bonded to a nonterminal carbon further than one carbon away from an aromatic ring, and hydrogen bonded to a methyl group that is not bonded to an aromatic ring. Infrared spectroscopy was also used to distinguish between ether and hydroxy oxygen and to distinguish between amines and other nitrogen groups.

Schwarz and Prausnitz[91] give detailed example calculations for converting raw characterization data to specific characterization parameters used in their perturbed-hard-chain equation of state. The procedure is not intended for calculations on conventional fossil fuels where experimental data on boiling points and densities are available. Instead the procedure is intended for heavy fossil fuels, where conventional correlations are unreliable or input data are unavailable.

Cookson and Smith[92] derived simple linear property–composition relationships for a range of 51 jet fuels and 48 diesel fuels using ^{13}C NMR alone. The relationships were of the form, Equation (3)

$$P = b_1 C_n + b_2 C_{ar} + c \tag{3}$$

where P is the property in question, b_1, b_2, and c are coefficients, and C_n is the fraction of total ^{13}C NMR signal intensity attributable to long-chain alkyl-carbon occurring at 32.3, 30.1, 29.8, 23.0 and 14.2 ppm. C_{ar} is the total aromatic carbon signal in the region, 110–160 ppm.

For jet fuels in the boiling range, 190–230 °C, the properties included smoke point, aromatics content, hydrogen content, heat of combustion, freezing point and specific gravity. For diesel fuels in the range 230–320 °C, the properties included pour point, cloud point, hydrogen content, aniline point, specific gravity, diesel index, and cetane index. The results are summarized in Tables 10 and 11. Of particular note is that the relationships all have the same form and use the same type of analytical information.

Table 10 Models for jet fuel properties based on NMR compositional parameters[a]

Property	Method	No. of samples	Range	Coefficients		
				b_1	b_2	c
Smoke point (mm)	IP57	44	15–38	25.7	−66.8	23.6
Aromatics content (vol%)	ASTM D1319	49	1.6–24.2	−1.1	139.4	2.4

4.3 Determination of Hydrogen Consumption During Processing

In the 1990s there has been a significant increase in residuum hydroconversion in refineries throughout the world. To a large extent, this expansion was derived from expectations that the spread in market values between high-sulfur fuel oil and light transportation fuels would increase to support the investments required for these conversion facilities.

Residuum conversion involves increasing the hydrogen-to-carbon (H/C) ratio and decreasing the molecular weight of the distillate products. However, because of the hydrogen imbalances, either carbon is rejected or hydrogen is added to achieve a desired product state. For those processes that involve hydrogen addition, NMR can be used effectively to determine the types of reaction that consume hydrogen under a given set of process conditions.

Finseth et al.[95] proposed a method to monitor the changes in hydrogen utilization during coal liquefaction. The same approach can be used to study the role of hydrogen during residuum upgrading.[96,97] This method incorporates analytical methods that are readily available. In the method of Finseth et al.,[95] the total hydrogen incorporated in the products during conversion is given by Equation (4)

$$\Delta H_T = \Delta H_{hyd} + \Delta H_{NOS} + \Delta H_{C1-C4} + \Delta H_{matrix} \qquad (4)$$

where ΔH_T is the total hydrogen incorporated, ΔH_{hyd} is the hydrogen incorporated by hydrogenation, ΔH_{NOS} is the hydrogen associated with heteroatom removal, ΔH_{C1-C4} is the hydrogen associated with hydrocarbon gas production, ΔH_{matrix} is the hydrogen incorporated in nonvolatile solid and liquid products owing to alkyl bond scission.

Thus, measurement of hydrogen incorporation during processing is reduced to measuring ΔH_T by elemental analysis, measuring ΔH_{hyd} by ^{13}C NMR aromaticity measurements in the solid and liquid reactants and products, and measuring ΔH_{C1-C4} and ΔH_{NOS} by quantitative gas analyses. The term ΔH_{matrix} is then determined by difference. If this term is negative, hydrogen is liberated because of condensation reactions. If ΔH_{matrix} is positive, then thermolysis reactions consume hydrogen during liquefaction.

The method assumes that, on average, one hydrogen atom is incorporated into the organic product for every heteroatom removed from the feed material; hydrogenation consumes one hydrogen atom for every carbon atom reduced (each 0.01 change in aromaticity); and two hydrogen atoms are consumed per mole of light hydrocarbons formed. The rationale for these assumptions is discussed in greater detail by Finseth et al.[95] and by Beret and Reynolds,[96,97] who also used the method to determine hydrogen incorporation in petroleum residuum hydroconversion.

Beret and Reynolds[96] applied this method to study residuum hydroconversion of three California residua processed at different severities using different sets of operating variables such as temperature, pressure, residence time, hydrogen circulation route and catalyst. The approach yielded a detailed description of hydrogen incorporation during residuum hydroconversion. Character of the feedstock, processing conditions, and catalyst all affected how hydrogen was incorporated into the residuum matrix. Hydrogenation and hydrocracking reaction incorporated hydrogen equally at moderate process severities (343 °C or 650 °F). At higher severities (454 °C or 850 °F), the bulk of the hydrogen was used to cap radicals generated from cracking reactions. Thus, by a judicious choice of operating conditions, certain hydrogen incorporation reactions could be favored over others. The feedstock also influences how hydrogen was incorporated. With aromatic feedstocks, hydrogenation reactions compete for hydrogen equally with hydrocracking. With less aromatic feedstocks, hydrocracking dominates over hydrogenation reactions.

In another study, Beret and Reynolds[97] used the method to study the effects of prehydrogenation on hydroconversion of Maya residuum. A Maya 343 °C (650 °F) residuum was prehydrogenated using a standard hydroprocessing catalyst. The 343 °C (650 °F) residuum of this product was then processed separately at selected conditions and the products analyzed to determine how hydrogen was incorporated during processing. The results were compared with direct hydroconversion. The distribution of hydrogen was dependent upon the type and severity of the process. In direct hydroconversion, about 25–30% of the total hydrogen was incorporated from heteroatom removal and hydrocarbon gas formation. The two-step process, which involved mild prehydrogenation, primarily incorporates hydrogen by hydrogenation reactions at the expense of C_4 gas formation and cracking, particularly at low severity. At moderate severity, cracking reactions occur but are suppressed to some extent. The real benefit came from suppression of C_4 gas formation.

4.4 Nuclear Magnetic Resonance Studies of Coking

Delayed coking is the most widely used petroleum residue conversion process in the world.[98,99] Although the process is about 60 years old, there are still many aspects of the chemical reactions taking place that are poorly understood. Of particular importance is the ability to predict product yield and quality from basic feedstock composition. Yield data are important for assessing process economics, and maximum conversion to liquid

products, primarily gasoline and distillate product is generally the main objective. Solid- and liquid-state NMR techniques can provide useful information about delayed coking processes similar to that described in the previous section. Complete NMR characterization (^{1}H and ^{13}C) of a feedstock and delayed coking products, coupled with material balances, can be used to obtain the distribution of carbon and hydrogen atoms in a delayed coking process.

Rodriguez et al.[98] used such an approach to study the delayed coking of a fluid catalytic cracker decanted oil in a pilot plant operation that simulated a conventional commercial operation. They demonstrate how to perform the material balance to reveal changes in the carbon and hydrogen distributions resulting from carbonization reactions during delayed coking. Rodriguez et al.[99] found a significant increase in the number of aromatic carbons, which was due mainly to an increase in the number of quaternary aromatic carbons. This was interpreted as an increase in the extent of condensation reactions.

4.5 Process Kinetics

The reactions that occur during catalytic and thermal upgrading of crude oil are very complex and involve a large number of interacting species. In such complex mixtures, it is not possible to have a knowledge of all the interacting species. Consequently, lumped kinetics methods, wherein similar reactive species are grouped together to develop rate constants, have been developed to analyze reactions in complex mixtures.[100] Lumping can be used to reduce the number of experiments required

Figure 15 Assignment of carbon and hydrogen types to groups in regions of the ^{13}C and ^{1}H NMR spectra. (Reproduced with permission from M.R. Gray, *Ind. Eng. Chem. Res.*, **29**, 505–512 (1990).[100] Copyright (1990) American Chemical Society.)

to define the kinetic behavior of the reacting system, simplify the network of possible reaction paths, and reduce the overhead of analytical work required to define component-by-component compositions.

NMR spectroscopy provides a method for estimating the concentrations of a selected set of groups to be used in lumped kinetics as long as the sample is soluble in an appropriate solvent. Data from NMR analyses can be combined with elemental analyses to obtain concentrations of structural groups. The main structural groups that can be estimated by combining NMR with elemental analysis are shown in Figure 15. The spectra in Figure 15 are typical of heavy oils and illustrate the regions where signals appear from the different structural groups. The assignment of groups to the ^{13}C NMR spectra involves some approximations that are due to overlapping peaks. The lack of sharp signals (except for paraffinic CH and CH_2) is due to the large number of isomeric compounds that have overlapping resonances. NMR provides a unique way of monitoring changes in the concentrations of these groups independent of molecular weight so long as the samples are soluble. Insoluble material can be analyzed by solid-state NMR, but less structural information can be deduced.

An example of the use of lumped kinetics in petroleum upgrading is that of Gray.[100] Data from thermal and catalytic hydrotreating of a Syncrude coker gas oil in a continuous-stirred reactor were used to study lumping of reaction kinetics based on structural groups. Feed and product compositions were described by a limited set of aliphatic and aromatic carbon groups, based on data from elemental analysis and ^{1}H and ^{13}C NMR spectroscopies. The study demonstrated that stoichiometric relationships or ratios between groups can be deduced from rate data, even in complex mixtures. These ratios could then be used to construct models for hydroprocessing. For example, the rate of heteroatom removal can be used to predict changes in the carbon aromaticity of the oil, which in turn, can be used to estimate the CN.

ABBREVIATIONS AND ACRONYMS

AMW	Average Molecular Weight
ASTM	American Society for Testing and Materials
CN	Cetane Number
COSY	Correlation Spectroscopy
CP	Cross-polarization
DD	Dipolar Dephasing
DEPT	Distortionless Enhancement by Polarization Transfer
FID	Free-induction Decay
GASPE	Gated Spin-echo ^{13}C NMR
H/C	Atomic Hydrogen to Carbon
HETCOR	Heteronuclear Correlation
MAS	Magic Angle Spinning
NMR	Nuclear Magnetic Resonance
NOE	Nuclear Overhauser Enhancement Effect
PETSOL	Petroleum Solvent
QUAT	Quaternary Only Carbon Spectrum
RF	Radiofrequency
RON	Research Octane Number
SEBBORD	Spin-echo Broad-band Off-resonance Decoupling
S/N	Signal-to-noise Ratio
SPE	Single-pulse Excitation
TKS	*Tetrakis*(trimethylsilyl) silane
TMS	Tetramethylsilane
TOC	Total Organic Carbon
UOP	Universal Oil Product
VPO	Vapor Pressure Osmometry
2D	Two-dimensional

An oil shale can be defined as a compact rock of sedimentary origin with an ash content of more than 33% and containing organic matter that yields oil when destructively distilled, but not appreciably when extracted with ordinary solvents. This is an operational definition. There is no geological or chemical definition of an oil shale. The term is used mostly in an economic sense so that any shallow rock that yields a commercial amount of oil upon pyrolysis may be considered an oil shale. Oil shale deposits occur in at least 50 countries and the estimated potential world supply of oil from shale is 5×10^{12} barrels.

The organic matter in an oil shale is mostly in the form of kerogen, which is defined as that fraction of the organic matter in a sedimentary rock that is insoluble in common petroleum solvents. The insolubility of kerogen is the main reason why an oil shale must be heated to produce liquid products. The amount of shale oil that can be produced by heating an oil shale is normally obtained from a Fischer assay. However, the Fischer assay is somewhat time-consuming and does not provide information about what chemical properties of oil shales are important for producing liquids. Consequently, a number of alternative procedures have been developed to analyze oil shales. These procedures, along with methods of analyzing shale oils, are described in the following sections.

1 INTRODUCTION

An oil shale can be defined as a compact rock of sedimentary origin with an ash content of more than 33% and containing organic matter that yields oil when destructively distilled, but not appreciably when extracted with ordinary solvents.[1] This is an operational definition. There is no geological or chemical definition of an oil shale. The term is used mostly in an economic sense so that any shallow rock that yields a commercial amount of oil upon pyrolysis may be considered an oil shale. The key words are ''commercial amount'' because petroleum source rocks, which often contain only 1% organic matter, can produce commercial amounts of oil over geologic times. On the contrary, oil shales must have a large enough fraction of organic matter to be of economic interest. The organic matter content of an oil shale should be ~2.5 wt%, just to provide the calorific requirements necessary to heat the rock to 500 °C in order to produce shale oils by thermal decomposition of the organic matter.[2] Below this amount of organic matter, the rock cannot be a source of energy because it takes more energy to heat the rock than can be derived from the produced shale oil. A lower limit of 5% organic matter is sometimes used to define a commercial deposit[2] although such a limit is subject to change depending on prevailing economic conditions. Thus, an oil shale can be a petroleum source rock if subjected to the proper burial conditions over geologic time, but a petroleum source rock at shallow depths is not an oil shale because of the requirement of organic matter richness.

Oil shales occur worldwide, span geologic time from Cambrian to present, and were deposited principally in large freshwater lakes (lacustrine environment), shallow seas and continental shelves (marine environment), and in small lakes, bogs and lagoons associated with coal-producing swamps (paludal environment). Oil shale deposits occur in at least 50 countries and the estimated potential world supply of oil from shale is 5×10^{12} barrels. Shale oil industries in Scotland, Australia, France, Russia and China have been active over the years since about

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

1860.[3] In Australia, France and Scotland oil shales have been the source of products similar to those obtained from petroleum. However, the discovery of petroleum in the United States in 1859, and elsewhere soon afterwards, caused the demise of the economic production of shale oil, and the situation remains much the same today. Limited but continued use of oil shale as an energy resource has been made since about 1909 in China and 1916 in Russia. In Brazil, a pilot plant has been in operation since 1982 and has produced over three million barrels of shale oil. Oil shale is being used for some power generation in Israel.

The Green River Formation in Colorado, Utah, and Wyoming, USA has been the most extensively studied oil shale formation in the world. A summary of core data and samples collected by the US Geological Survey has been published.[4] Table 1 summarizes the number of Fischer assays performed on Green River Formation oil shales. During the 1970s, there was significant oil shale activity ongoing in the United States. Tracts of oil shale lands in the Green River Formation were leased for commercial development in 1974 and the decade between 1974 and 1984 represented the greatest activity ever in oil shale research in the US. Partly, this was caused by the oil embargo of 1973, the leasing of the oil shale tracts in Colorado and Utah in 1974, and the creation of the US Department of Energy in 1976. This activity spawned a variety of methods for analyzing oil shale. However, in the year 2000 oil shale activity has all but ceased in the US. Understandably, the plentiful supply and low cost of petroleum has suppressed the commercialization of oil shale and other fossil fuel conversion processes (tar sand processing and coal liquefaction).

The organic matter in an oil shale is mostly in the form of kerogen, which is defined as that fraction of the organic matter in a sedimentary rock that is insoluble in common petroleum solvents. Another fraction, bitumen, is defined as that fraction of the organic matter in a sedimentary rock which is soluble in common petroleum solvents. Kerogen constitutes the major portion of the organic matter (~90% or greater), and its insolubility is one reason why an oil shale must be heated to produce liquid products. Because of kerogen's insolubility, it has been very difficult to obtain information about the chemical structure and composition of kerogen. Compositional data can be acquired after first carrying out laborious and time-consuming procedures to remove minerals and to prepare kerogen concentrates.[5] For an introduction to oil shales and kerogen, the reader is referred to books and reviews that are available.[2,3,5–12]

Table 1 Summary of Fischer assay analyses of the Green River Formation oil shale deposits in Colorado, Wyoming, and Utah (modified from Dyni et al.[4])

	Colorado	Wyoming	Utah	Totals
Number of drill holes analyzed	389	63	153	605
Number of Fischer assays	206 000	13 000	32 000	251 000

2 OIL SHALE ASSAY METHODS

To evaluate the potential of an oil shale formation as a future source of liquid hydrocarbons, two important factors must be considered: (1) how much organic matter is in the formation, (2) how much of the organic matter can be converted to oil. The first factor relates to the total quantity of organic matter in the sediment, while the second factor relates to the quality or type of organic matter.

2.1 Thermal Methods

2.1.1 The Fischer Assay

Probably the single most important item of information about an oil shale is its potential to produce oil during heating. The traditional method for evaluating the potential oil yield of an oil shale is the Fischer assay [ASTM (American Society for Testing and Materials) method D-3904-80].[117] The Fischer assay consists of heating a 100 g sample of −8 mesh (2.38 mm) particle size oil shale to 500 °C at 12 °C min^{-1} and maintaining this temperature for 40 min. During this heating cycle, hydrocarbon vapors are distilled from the rock and condense to form a shale oil. The material is collected, and its volume and weight and specific gravity are recorded. From these measurements, the oil potential is reported in gallons of oil per ton of shale (or liters per tonne, depending upon one's preference for units). Obviously the greater this number, the greater the commercial viability of the formation.

The Fischer assay is strictly a specification test. It does not provide any information about the quality of the organic matter in the oil shale. Nevertheless, it is the benchmark for evaluating an oil shale deposit, and also for determining the efficiencies of oil shale retorting processes. For issues involving exchange or leasing agreements of public oil shale lands in the western United States, the Fischer assay is the only accepted method to determine the value of the lands in question.

Because the Fischer assay does not provide information about what chemical properties of oil shales are important for producing liquids, a number of studies have been made to correlate various chemical and physical property measurements with oil yields determined by the Fischer assay. Even the Fischer assay procedure has been

Table 2 Summary of methods of correlating kerogen properties with oil yields

Method	Measured property	Refs.
Elemental analysis	Organic carbon, total hydrogen	16, 17
Laser pyrolysis	Acetylene yield	18, 19
Thermal analysis	Weight loss and evolved gases upon heating	20, 21
Thermophysical	Thermal conductivity, thermal diffusivity, relative dielectric constant	22–25
Densimetric	Oil shale density	26, 27
FTIR spectroscopy	Aliphatic hydrogen	28, 29
ESR	Unpaired electron concentration	30, 31
NMR pulsed	Total hydrogen	32–35
CP/MAS	Aliphatic/aromatic carbon distribution	28, 36–41

FTIR, Fourier transform infrared; ESR, electron spin resonance; NMR, nuclear magnetic resonance; CP/MAS, cross-polarization/magic-angle spinning.

modified to assay different types of oil shale, or to resemble, more closely, a certain type of retorting process.[13–15] Other reasons for the development of alternate assay methods are that the Fischer assay is fairly time-consuming and the desire to have on-line assaying methods at an oil shale retort.

A summary of some methods for correlating oil shale properties with Fischer assay oil yields is given in Table 2. In general, these methods attempt to measure a parameter that is associated with the quantity of organic matter in the sediment and do not take into account the quality of the organic matter, i.e. its chemical structure. As such, most of them are specific to a given oil shale formation. For example, a correlation derived for oil shales from the Green River Formation in Colorado in the United States is probably not valid for a different oil shale formation, such as, for example, oil shales from the Rundle Deposit in Queensland, Australia. A new correlation must be established for every new deposit.

2.1.2 Elemental Analyses

The elemental composition of an oil shale can be correlated with oil yields determined by the Fischer assay.[16,17] The best correlation for Green River Formation shales is between organic carbon and Fischer assay oil yields. This is not surprising since organic carbon constitutes the major element in the composition of an oil shale. Cook[16] obtained Equations (1) and (2) for oil yield based on weight percent (wt%) or gallons per ton

$$\text{Oil (wt\%)} = 0.832\,(\%\text{orgC}) - 0.251 \qquad (1)$$

$$\text{Oil (gal ton}^{-1}\text{)} = 2.22\,(\%\text{orgC}) - 0.771 \qquad (2)$$

where %orgC is the wt% organic carbon. These correlations were obtained prior to the development of solid-state NMR techniques. However, it is of interest to note that the coefficient of 0.832 in Equation (1) is close to the fraction of aliphatic carbon (0.80) in Green River Formation oil shale determined by ^{13}C-NMR measurements.[36] The aliphatic carbon content for any oil shale has been shown to be a good indicator of oil yield.[28,36–41]

For Devonian (Cleveland member) and Mississippian (Sunbury member) black shales from the eastern United States, organic carbon also correlates with Fischer assay oil yield (Figure 1).[17] However, because of differences in maceral compositions (quality) of the organic matter in different deposits,[42] the data are best fit with separate regressions for deposits from different geologic ages.

If the quality of the organic matter does not change significantly in the formation, then correlations based on organic carbon are applicable, and organic carbon content is a good indicator of the quantity of organic matter in the sediment. As a rule of thumb, the Fischer assay oil yields in gal ton^{-1} for Green River Formation oil shales are about 2–2.5 times %orgC. For Devonian oil shales from the eastern United States, the oil yields in gal ton^{-1} are about

Figure 1 Plot of Fischer assay oil yields and carbon contents for Cleveland and Sunbury oil shales. (Reprinted with permission from T.L. Robl, A.E. Bland, D.W. Koppenaal, L.S. Barron, 'Geochemistry of Oil Shales in Eastern Kentucky', in *Geochemistry and Chemistry of Oil Shales*, eds. F.P. Miknis, J.F. McKay, ACS Symposium Series 230, American Chemical Society, Washington, 159–180, 1983. Copyright 1983 American Chemical Society.)

equivalent to %orgC. For the shales from eastern Kentucky (Figure 1), the Sunbury and Cleveland shales produce 1.03 and 1.18 gal of oil per unit %orgC, respectively.

2.1.3 Laser Pyrolysis

Laser pyrolysis chromatography has also been suggested as a method for analyzing oil shales.[18,19] The method involves using a laser to rapidly pyrolyze the kerogen in an oil shale, followed by detection of the pyrolysis products by gas chromatography (GC). Because of the extremely high temperatures involved during the pyrolysis, acetylene is the major organic species in the product gas mixture. The amount of acetylene produced correlates with the oil yield. With a flame ionization detection (FID) probe only organic species are detected so that the integrated chromatogram is proportional to the amount of organic matter. Some disadvantages of the technique are that the oil shale must be ground, then pelletized before analysis. Because the laser is focused onto a small area, it is important that the pellets be uniform in oil shale composition so that the samples are representative of the deposit. Also, it is important that the amount of laser energy absorbed by the sample be the same for each laser pulse in order to achieve reproducibility.

2.1.4 Thermal Chromatography

A procedure for assaying oil shales based on thermal analytical methods has been suggested.[20,21] This method is a low-temperature method compared with laser pyrolysis. In the thermal chromatographic method, an oil shale is heated ($\sim$30 °C min^{-1}) to a temperature of 600 °C. Hydrocarbon gases that are evolved during heating are measured with a gas chromatographic flame ionization detector. The total amount of evolved gases correlates with the Fischer assay oil yields. A disadvantage of this procedure is that small sample sizes (milligrams) must be used; therefore, sample homogeneity and particle sizes could present problems. An advantage is that the evolved gases can be analyzed by GC to obtain information about the organic matter just as in laser pyrolysis. These methods are similar to the Rock-Eval pyrolysis method used in geochemical analyses for determining kerogen type and maturity.[2] Rock-Eval measurements have been shown to correlate with Fischer assay oil yields.[1]

2.1.5 Microwave and Thermophysical Methods

Microwave radiation has been suggested as an alternative heating method for assaying Colorado oil shales.[22] The dissipation of microwave energy has been shown to be a strong function of the richness of an oil shale. The loss tangent, which is an index of a material's ability to absorb microwaves and which is also related to the dielectric constant of the material, increases nonlinearly as shale richness increases linearly.

Thermal conductivity, thermal diffusivity, dielectric constant, specific heat and sonic velocity measurements have been made as a function of oil shale richness.[23–25] However, none of these measurements appears promising as a method for assaying oil shale. In some cases, the measurements are dominated by the mineralogy. In addition the correlations are nonlinear, as are the microwave correlations, which tends to detract from their usefulness as assay methods.

2.2 Nonthermal Methods

2.2.1 Density Measurements

A simple, but effective, correlation of a physical property measurement with oil yield is the relationship between density and oil yield.[26,27,43] These correlations are based on the simple observation that the oil shales having a high organic content are less dense than oil shales having a low organic content. Thus, by measuring the density of an oil shale, one is essentially measuring the weight fraction of organic matter in an oil shale. The relationship between density and weight percent organic content has been derived by Smith[26] and has the form shown in Equation (3)

$$D_T = \frac{D_A D_B}{A(D_B - D_A) - D_A} \tag{3}$$

where D_T is the absolute density of the oil shale; D_A is the average density of the organic fraction; D_B is the density of the inorganic fraction; and A is the weight fraction of the organic matter. Equation (3) is a general expression and is applicable to any oil shale deposit. For Green River Formation oil shales, D_A is about 1.07, and D_B is about 2.72 g cm^{-3}.[27] An expression relating oil yield in gal ton^{-1} and density for Green River oil shale is shown in Equation (4).

$$\text{Oil (gal ton}^{-1}) = 31.6D_T^2 - 206.0D_T + 326.6 \tag{4}$$

Schultz and Bates[43] have correlated oil yields with oil shale density for oil shales and beneficiated products from oil shales from Alabama, Indiana, Kentucky, Ohio, Michigan and Tennessee. Their correlation between oil yield and densities is shown in Equation (5).

$$\text{Oil (gal ton}^{-1}) = 29.9D_T^2 - 173D_T + 250.3 \tag{5}$$

For New Albany oil shales from Kentucky, oil yields have also been shown to correlate with specific gravity and sound velocity measurements. The latter is somewhat redundant because sound velocity depends on density.[44]

The method relating density to organic content only works well if the mineral and organic components are fairly uniform throughout the deposit, and the percentage conversion of organic matter to oil is uniform. If not, these types of correlations must be developed for each oil shale deposit. These conditions apply to all correlations that measure some chemical or physical property that relates to the quantity, and not to the quality, of the organic matter.

2.2.2 *Spectroscopic Methods*

2.2.2.1 Fourier Transform Infrared FTIR spectroscopic measurements have been applied to obtain information about the aliphatic components in oil shales.[28,29] Spectra are recorded from 4000 to 400 cm^{-1} and corrections are applied for particle scattering and mineral interferences. The CH stretching bands between 3100 and 2750 cm^{-1} are used to obtain a measure of the aliphatic carbon contents, which are then correlated with the Fischer assay oil yields. The FTIR methods have not been widely accepted for studying oil shales. One reason is that, because of the small sample sizes used, obtaining a representative sample is a concern.

2.2.2.2 Electron Spin Resonance Attempts have been made to correlate ESR measurements with oil yields.[30,31] The assumption behind these measurements is that the organic free-radical concentration might correlate with oil yield. Stable organic free radicals are associated with aromatic components, whereas oil yield is more closely associated the hydrogen-rich aliphatic components. Unfortunately unpaired electrons from the minerals also contribute to the ESR signal. Nevertheless, for a set of Colorado oil shales from the same core, the ESR signal gives a fair correlation with oil yields. However, in the case of eastern US oil shales, no correlation between ESR measurements and oil yield was found when samples from different locations were analyzed.[31]

2.2.2.3 Proton (^1H) Nuclear Magnetic Resonance It is reasonable to assume that the amount of hydrogen in an oil shale should be an indicator of the potential oil yield of an oil shale because the amount of available hydrogen is a key factor in producing liquids during pyrolysis. Consequently, correlations have been developed between hydrogen content and Fischer assay oil yields.[32–35] These were based on the use of pulsed NMR methods, in which the signal amplitude measured immediately after a 90° pulse is directly proportional to the amount of hydrogen in the shale. A comparison of a Fischer assay oil yield histogram and a pulsed NMR hydrogen response histogram is shown in Figure 2. The NMR response, which is in arbitrary units, quite faithfully mimics the Fischer assay histogram. Some advantages of pulsed NMR methods are that they are rapid and nondestructive, and can be easily automated. They could be used for rapidly screening an oil shale deposit. Disadvantages are small sample sizes, and interferences due to protons in water and clay minerals. Also, because pulsed NMR provides a measurement of total hydrogen, and not just organic hydrogen, calibrations must be established for each oil shale deposit.

Figure 2 Comparison of depth profile histograms of Fischer assay oil yields and pulsed NMR response for a set of 141 Colorado oil shales. (Reproduced with kind permission from Kluwer Academic Publishers from F.P. Miknis, 'Methods of Oil Shale Analysis', in *Composition, Geochemistry, and Conversion of Oil Shales*, ed. C. Snape, NATO ASI Vol. 455, Kluwer Academic Publishers, The Netherlands, 191–209, Figure 2, 1995.)

2.2.2.4 Carbon (^{13}C) Nuclear Magnetic Resonance Except for the FTIR measurements, the assay methods described in the previous sections have one thing in

common. They all measure, or attempt to measure, some physico-chemical parameter associated with the amount (quantity) of organic matter in an oil shale. While these methods might provide reasonably good correlations with oil yields, they are generally only valid for a specific deposit, and only valid if the type of organic matter, or its composition, does not vary significantly throughout the deposit. None of the methods provides much insight into what chemical structures are important for producing shale liquids during pyrolysis of oil shales.

The importance of kerogen structure in the conversion behavior of oil shales has been known for a long time.[6] However, it was only with the development of solid-state ^{13}C-NMR techniques that direct information about the carbon structure could be obtained. An example of the importance of kerogen chemical structure for producing shale oil is illustrated by the ^{13}C-NMR spectra shown in Figure 3. The total organic carbon is essentially the same for the three oil shales; however, the percentage of conversion of organic carbon to oil during Fischer assay retorting is different for the three shales. The CP/MAS solid-state ^{13}C-NMR spectra show clear differences in the carbon distributions of the oil shales. Most of the organic carbon in the Colorado oil shale is in the form of aliphatic carbon structures (0–50 ppm), whereas a substantial portion of the organic carbon in the Kentucky oil shale is in aromatic carbon structures (100–150 ppm). The oil shale from Morocco has a carbon distribution in between. These data provide a quantitative basis for previous concepts that kerogens with a high H/C ratio (ca. 1.5 or more), so-called Type I kerogens, produce greater quantities of oil during maturation than do Type III kerogens which have an H/C ratio less than unity.[2]

Figure 3 CP/MAS ^{13}C-NMR spectra of oil shales illustrating importance of kerogen structure in conversion to oil.

Figure 4 Correlations between aliphatic carbon and total carbon with Fischer assay oil yield. (Reproduced with kind permission from Kluwer Academic Publishers from F.P. Miknis, 'Methods of Oil Shale Analysis', in *Composition, Geochemistry, and Conversion of Oil Shales*, ed. C. Snape, NATO ASI Vol. 455, Kluwer Academic Publishers, The Netherlands, 191–209, Figure 4, 1995.)

By combining the NMR measurements of aliphatic carbon ratios of the kerogen, with organic carbon contents of kerogen, good correlations have been obtained that are independent of depositional environment, geographic location or geologic age.[28,36–41] In Figure 4, correlations are shown between Fischer assay oil yields and total organic carbon and aliphatic carbon for 55 oil shales from different deposits around the world. The data clearly show that chemical structure, i.e. aliphatic carbon, is important for producing shale oils during retorting.

3 COMBINED USE OF NUCLEAR MAGNETIC RESONANCE AND THE MATERIAL BALANCE FISCHER ASSAY TO STUDY OIL SHALE PROCESS CHEMISTRY

The effects of kerogen chemical structure on the conversion behavior of oil shales can be studied by combining solid- and liquid-state NMR measurements with material balance Fischer assay data. In a material balance Fischer assay the elemental composition is determined for the raw shale and the gas, oil and spent shale products. The elemental composition of the gas is calculated from the gas composition which is determined by GC. The assay data can be normalized to the basis of 100 carbon atoms, from which the percentage of carbon in the different products can be calculated. The percentage of organic carbon in the raw shale can be used as an indicator of the quantity of organic matter (kerogen) in raw shale. From these combined measurements, insight into some of the chemistry of kerogen decomposition can be obtained. A knowledge of the chemistry of kerogen decomposition could lead to more efficient retorting processes.

In this section, the effects of carbon structure on the conversion behavior of several oil shales are described for a set of ten oil shales from different deposits around the world.[45] Material balance Fischer assay data are given in Table 3, and normalized NMR conversion data are given in Table 4. During pyrolysis, there is an increase in the amount of aromatic carbons in the products (oil plus residue) over that in the original shale.[46,47] This increase is produced at the expense of aliphatic carbon moieties, which produce aromatic carbon by dehydrogenation of hydroaromatic structures and by ring closure of alkyl groups followed by dehydrogenation.[48] The combined use of solid- and liquid-state ^{13}C-NMR, in conjunction with the material balance Fischer assay conversion data, allows some inferences to be made about the extent of aromatization reactions during heating. The Alaska shale has the greatest loss of aliphatic carbons (22) to aromatization reactions (Table 4). The Australia, Kentucky, Morocco

[a] Ratio of residue aromatic carbon to raw shale aromatic carbon.
[b] Ratio of residue aliphatic carbon to raw shale aliphatic carbon.

and Turkey shales also show substantial losses of aliphatic carbons to aromatization reactions. When expressed as a percentage of the raw shale aliphatic carbons, a more realistic comparison of the importance of aromatization reactions for the shales is obtained (Table 4). The Kentucky, Morocco and Turkey–Seyitömer oil shales show the greatest percentage decrease in aliphatic carbons. These shales also show the lowest carbon conversions to oil and the highest carbon conversions to residue.

The implication of these observations is that coking (aromatization) reactions are more prevalent in the Kentucky, Morocco and Turkey–Seyitömer shales. However, it cannot always be established to what extent these reactions occur in the solid or liquid state. For the Alaska shale the net effect of the aromatization reactions is to produce oil, because the number of aromatic carbons (16) in the raw shale is not sufficient to account for the number of aromatic carbons (25) in the oil. For the remaining shales, the number of aromatic carbons in the shale oil is substantially less than the number of aromatic carbons in the raw shale. Consequently, the origin of the aromatic carbons in the shale oil is not conclusive. In the case of the Kentucky shale, the number of aromatic carbons (49) in the raw shale is not sufficient to account for the number of aromatic carbons (56) in the residue. Therefore, at least seven of the raw shale aliphatic carbons are converted to aromatic carbons in the residue. This assumes that coking of the shale oil vapor does not occur during Fischer assay.

A plot of the ratio of the number of aromatic carbons in the residue versus the number of aromatic carbons in the raw shale is shown in Figure 5. If this ratio is greater than unity, then the minimum number of aliphatic carbons that have aromatized to form residue can be determined. If the ratio is less than unity, the source of the residue aromatic carbons cannot be determined. Figure 5 shows that the Australia, Kentucky and Turkey–Seyitömer oil shales have ratios greater than unity, suggesting that the aromatization reactions to form coke are most prominent in these shales. The Morocco, China–Maoming and Turkey–Göynük shales have ratios close to unity (>0.93). Except for the Turkey–Göynük shale, all of the shales with ratios greater than or near unity show the lowest aliphatic carbon conversions to oil during Fischer assay. The data in Figure 5 suggest that the shales can be divided into three groups with regard to coking tendency, based on the ratio of residue aromatic carbon to raw shale aromatic carbon. Thus, the coking tendency is Australia, Kentucky, Turkey–Seyitömer > China–Maoming, Morocco, Turkey–Göynük > Alaska, Brazil, China–Fushun, Colorado.

Some of the aliphatic carbons in the kerogen end up as aliphatic carbons in the residue. Although these carbons are not involved in coking reactions, they represent a loss in oil potential. These carbons are most likely short-chain (methyl, ethyl) aliphatic carbons attached to aromatic rings. Figure 6 shows the aliphatic carbon content of the residue, expressed as a percentage of the raw shale aliphatic carbon. The interesting feature of these data is that this percentage is in the 10–20% range for most of the shales, independent of kerogen structure and conversion behavior.

4 SHALE OIL ANALYSIS

4.1 Introduction

The physical properties and the chemical compositions of shale oil depend on the source of the raw shale and the type of process used to obtain the oil. Shale oil can be obtained from oil shales by in situ and ex situ (surface) retorting. Laboratory quantities of shale oil for comparative studies and analytical methodology development are often obtained by the Fischer assay method.[49] Chemical analyses of shale oils produced by various retort methods have been used to compare oil shale properties from different locations[50–52] and with depth of the deposit[53,54] and to monitor and/or determine optimum retorting parameters.[55,56] Basically, shale oils differ from petroleum primarily in that they have a higher nitrogen content, and because shale oils are produced by pyrolysis, they contain higher concentrations of olefins, which are generally found in natural crude oils in low concentrations, if at all. Because of these materials, shale oils are relatively thermally unstable,[50] have poor long-term storage stability, and require modifications of the analytical methods used for petroleum characterization.

4.2 Separation Methods

Shale oils as well as other fossil fuels are complex mixtures of hydrocarbons and heteronuclear molecules. Thus, it is necessary to separate them into fractions in order to obtain information on molecular types and to identify individual compounds. The separation techniques most often used are distillation, simulated distillation, and various forms of chromatography – gas, liquid, ion-exchange chromatography (IEC), size-exclusion chromatography (SEC) and high-performance liquid chromatography (HPLC). In addition, shale oils often contain substantial amounts of water that interfere with fractionation of the oil using the various separation techniques and subsequent analyses. Generally, water is removed by distillation using a standard ASTM method.[57]

The elemental composition of the dried oil is determined using commercially available standard combustion instrumentation. Oxygen content is usually obtained by difference. Heating value of the shale oils can be computed from the elemental analysis data and the Boie equation (Equation 6).[58]

$$H = 8400(C) + 27765(H) + 1500(N) + 2500(S) - 2650(O) \quad (6)$$

where H is the gross heating value in cal g^{-1}, and C, H, N, S and O are the normalized weight fractions of these elements in the shale oil. Other properties such as specific gravity, viscosity and pour point are also determined on the raw shale oil using standard ASTM procedures.[59–61] Table 5 lists the elemental composition, carbon and hydrogen aromaticity values, molecular weights and specific gravity for Fischer assay shale oils from different oil shale locations worldwide.

Table 5 Elemental analyses, aromaticities, molecular weights and specific gravities of material balance Fischer assay shale oils

4.2.1 Distillation Techniques

4.2.1.1 Hempel Distillation Much of the early work on the characterization of shale oil used the Hempel distillation method[62] to obtain shale oil fractions having boiling point ranges similar to petroleum fractions obtained by distillation. In this method the crude shale oil is distilled into 14 subfractions, each having a boiling range of 25 °C. The first seven subfractions are collected at 760 mmHg (25–200 °C) and the remaining seven subfractions at 40 mmHg (200–350 °C). Specific gravity is measured on all subfractions, including the residue, and the viscosity is measured on fractions 11–14. The residue is analyzed for carbon residue and ash content to give an indication of carbon particulates and mineral matter in the oil.[50,51] Subfractions 1–7 are combined to give the naphtha fraction (25–200 °C), subfractions 8–10 to give the light distillate fractions (106–200 °C at 40 mmHg), and subfractions 11–14 to give the heavy distillate fraction (200–300 °C at 40 mmHg).

Naphtha Fraction. Figure 7 is a schematic diagram of the procedure used to separate further the shale oil naphtha fraction into numerous fractions using an efficient fractionating column for the identification of the compound types and individual compounds.[55,63] Naphtha distillates from crude shale oils produced by several methods of retorting Colorado oil shale were analyzed and found to be remarkably similar. The results indicate that the approximate composition of raw shale oil naphtha is: paraffins and naphthenes 30%; olefins 40%; aromatics 20%; sulfur, nitrogen and oxygen compounds 10%. Paraffins and aliphatic olefins, which comprise about two-thirds of their respective groups, are predominantly straight-chain compounds. The sulfur, nitrogen and oxygen are present principally in the form of thiophenes, pyridines and phenols, respectively.

Light Distillate Fraction. The shale oil distillate fraction that has received the least attention is the light distillate. This is the fraction that boils between 106 and 200 °C at 40 mmHg (equivalent to the 200–300 °C range if it were obtained at 760 mmHg). Analysis of the neutral oil obtained from the light distillate fraction[64] showed the paraffins and naphthenes content to be 10%, olefins 29% and aromatics 61%. The percentages of tar acids and bases were not determined.

Heavy Distillate Fraction. A series of separation techniques, outlined in Figure 8, has been applied to the heavy distillate from Colorado shale oil.[65] The techniques used were adsorption employing several different absorbents, vacuum distillation, thermal diffusion and complex formation. The hydrocarbon content made up approximately half of the heavy distillate (57%). Concentrates obtained from the heavy distillate were those composed of nitrogen compounds (43%) and aromatic, saturated and olefinic hydrocarbons (57%). The concentrates containing the saturates and olefinic materials (35%) were further subdivided into straight- and branched-chain compounds, and the aromatic concentrate (22%) was subdivided into fractions containing different numbers of condensed aromatic rings. For the nitrogen concentrate, separation was made into fractions containing different relative percentages of basic and nonbasic nitrogen.

4.2.1.2 Simulated Distillation Simulated distillation technique is a temperature-programmed gas–liquid chromatographic procedure for determining the distillation profiles of crude oils.[66] The chromatographic data are divided into desired distillate fractions from correlations between GC retention times and normal alkane boiling points. The concentration (wt%) of each distillate fraction is determined using response factors obtained from standard samples. The results

Figure 7 Separation scheme used to analyze the naphtha fraction from shale oil.

are reported as concentration (wt%) of distillable material versus temperature.[67] The boiling ranges of the fractions are chosen to correspond to the true boiling point distillation range of typical crude oil fractions.

The simulated distillation properties of the different Fischer assay shale oils[45] from different oil shales worldwide are given in Table 6. The amount of distillate in each of the fractions does not differ significantly among any of the shale oils, except for possibly the residue. The bulk of the oil (>50%) distills in two boiling ranges, the atmospheric and vacuum gas oil fractions. The temperature at which 50% of the shale oil has distilled off is shown in Figure 9. The average 50% off temperature for all the shale oils is $369 \pm 16\,^{\circ}C$ (95% confidence). This temperature is close to the average temperature of petroleum crude atmospheric gas oil fractions, which is 374 °C.

4.2.2 Chromatographic Techniques

Shale oil and shale oil fractions are extremely complex mixtures and while individual identification of the major components is conceptually and technically possible, the task is exceedingly time-consuming. Thus, characterization of a shale oil or fraction thereof in terms of molecular class (saturates, olefins and aromatics) and average molecular properties of a particular shale oil or fraction is an alternative approach to individual compound identification. There are many chromatographic and extraction techniques which can be used to separate oil into chemical classes of organic compounds.

Adsorption displacement chromatography can be used to separate the shale oil distillates in the 200–325 °C boiling range into saturates, olefins and aromatic fractions.[68] Later papers[65,69] describe the methodology to separate a high-boiling shale oil distillate (gas oil) into

Figure 8 Separation scheme used to analyze the heavy distillate fraction from shale oil.

two concentrates using Florisil as an adsorbent (Figure 8). One concentrate contains most of the nitrogen compounds originally present in the distillate, and the other contains predominantly hydrocarbons. The hydrocarbon concentrate is then further separated into concentrates of aromatics, olefinic and saturated compounds by a two-step process, employing silica gel as the adsorbent. The aromatics are first removed from the saturates and olefins. These latter compounds are then separated from each other, using a much higher adsorbent/sample ratio than is used to remove the aromatics. Further separations of these concentrates are made by vacuum

Table 6 Simulated distillation fractions of material balance Fischer assay shale oils

Fraction	Boiling range (°C)	Wt% of shale oil fraction									
		Alaska	Australia Stuart	Brazil Irati	China Fushun	China Maoming	Colorado Anvil Pts	Kentucky Sunbury	Morocco Timahdit	Turkey Göynük	Turkey Seyitömer

distillation, thermal diffusion, adduct formation or additional adsorption techniques.

Elution chromatography can be used to separate shale oils into various fractions.[52] Typically, the column is packed with two-thirds silica gel topped with one-third alumina. The linear aliphatic and alicyclic hydrocarbon fraction is first eluted using a light petroleum followed by dichloromethane to elute the aromatic hydrocarbons and thio-aromatics. Methanol is used last to elute the polar nitrogen, sulfur and oxygen fractions. Separation of the aliphatic/alicyclic hydrocarbon fraction into saturates and unsaturates (olefins) is achieved by thin-layer chromatography (TLC) using plates coated with 0.5-mm thick silica gel and containing 10% silver nitrate. Branched and cyclic hydrocarbon fractions are separated from saturated fractions by urea adduction. Oil shales from different locations can be compared using the weight percents calculated for the various fractions.

Hydrogen types and polar materials, including acids and bases in shale oil distillates, can be determined using a combined subtraction and gas chromatographic technique.[70] This method consists of adding an appropriate internal standard to the sample, applying a specific subtraction technique and determining the amount of a compound type from comparison of the before and after gas chromatograms. The precision and detection limits are set by the precision of the gas chromatographic readout at about ±1%. The subtraction technique with GC readout is not useful for trace analyses. However, the data for compound types present in shale oil at the level of a few per cent allow use of the method for more detailed characterization of polar materials.

Brown et al.,[71] using gas–liquid chromatographic separation and spectrometric techniques, have identified 50 individual compounds in the nitrogen base fraction obtained from a hydrocracked shale oil naphtha fraction. They found that alkylpyridines comprised about 64% of the bases and alkylanilines about 33%. The rest of the bases were quinoline and small quantities of cycloalkanopyridines.

Preparative liquid chromatography and glass capillary GC were used to separate shale oil hydrocarbons into fractions of alkanes, alkenes and aromatics.[72–74] In addition, resolution of individual components of branched and cyclic alkanes and alkenes was achieved using a vapor-phase subtraction technique employing 100–200 mesh molecular sieve 5A. A chemically bonded pyrrolidone substrate was used for the HPLC[74] to separate polycyclic aromatic hydrocarbons (PAH) according to the number of aromatic rings and the type of ring condensation.

4.3 Spectroscopic Methods for Shale Oil Analyses

One of the first reported uses of instrumental methods of analysis for crude shale oil fractions was by Ball et al.[55] Using ultraviolet (UV) absorption spectroscopy these authors qualitatively identified numerous aromatic compounds in the naphtha fraction obtained from the distillation of crude shale oil. Dinneen et al.[65] used the technique to investigate high-boiling shale oil distillate. UV spectroscopy was also used in the investigation of the types of sulfur and nitrogen compounds in shale oil.[75–79]

Infrared (IR) spectroscopy was first applied in 1952 to the identification of tar acids[80] isolated from shale oil and later was used to confirm the straight-chain character of the urea–hydrocarbon adduct for saturated and olefinic fractions.[64,65] In 1956 Cook and Church[81,82] used IR spectroscopy to study the pyridine compounds isolated from shale oil tar base fractions. In succeeding years, other nitrogen-type compounds in shale oil also were identified by IR spectroscopy.[56,71,78,79,83] Olefin types found in shale oil were characterized by IR spectroscopy as early as 1960[84] and later by Jackson et al.[85] The polar constituents as well as normal and isoprenoid hydrocarbons isolated from oil shale bitumen and kerogen were studied by Robinson and co-workers.[86–89]

Mass spectrometry (MS) has been used extensively as an analytical tool in the petroleum industry. Thus, it is not surprising that MS has also been applied to shale oils. MS, as an analytical tool, was used by Van Meter et al.[90] to evaluate the Dumas procedure for determining the nitrogen content in shale oils. The first reported use of MS for the identification of hydrocarbons in shale oil was in 1952 by Dinneen et al.[80] A more extensive use of MS for the characterization of saturates and olefins in shale oil was reported by Jensen et al.[91] Normal,[86] isoprenoid[86] and alicyclic[92] hydrocarbons, fatty acids[93] and other polar

constituents,[89,94] steranes[95] and substituted tetralins in oil shale bitumens also have been identified using MS. Using the combined techniques of gas chromatography/mass spectrometry (GC/MS), Morandi and Guffey[96] identified isoprenoids, steranes and terpanes in a Fischer assay shale oil. Ciccioli et al.[97] used the GC/MS technique to study New Albany Shale, and Jones et al.[98] also characterized shale oils and related fuels using the technique.

The application of MS to the analysis of olefins and mixtures of olefins is extremely difficult. However, since shale oil can contain as much as 30% olefinic materials, several studies directed toward the identification of olefins using MS were conducted based upon deuterium labeling[99,100] and derivatization[85] techniques. Earlier MS studies reported direct identification of aliphatic olefins[63] and diolefins.[84]

Morandi and Jensen[76,101] used the mass spectral technique to identify porphyrins in shale oil and oil shale. Other nitrogen compounds were also identified using MS in the raw, refined shale oils,[56,61,77] shale oil naphtha[71] and gas oil fractions.[69] Not only were the nitrogen compounds identified in shale oil by MS, but the sulfur compounds were also identified.[102,103] A compilation of mass spectra of organic sulfur compounds was published by Cook and Dinneen.[104]

Less common analytical techniques were also used to investigate shale oils. Fluorescence spectrometry was used by Hurtubise et al.[105,106] to characterize and identify polynuclear aromatic hydrocarbons in shale oil, and the first systematic study of the free-radical content in raw shale, shale oil and spent shale using electron paramagnetic resonance spectroscopy was reported by Sidwell et al.[30]

^{1}H-NMR techniques have been used extensively to rapidly characterize hydrocarbon types in petroleum. The first reported use of ^{1}H-NMR to study oil shale bitumen was in 1964 by Cummins and Robinson.[86] They used the technique to confirm the methyl branching characteristics of isoprenoid compounds. ^{1}H-NMR was also used to confirm the identity of both isoprenoid compounds and a number of polar constituents isolated from Green River oil shale. The ^{1}H-NMR characterization of saturates and olefins in shale oil was conducted by Jensen et al.[91] and Jackson et al.[85] Several papers were published on the use of ^{1}H-NMR to identify nitrogen compounds in shale oil.[71,77]

As in the case of ^{1}H-NMR, ^{13}C-NMR was first applied to petroleum crude oil investigations and coal liquid fractions. NMR has been used to characterize hydrocarbons in shale oil[107] and to study oil shale in the solid state.[37] Netzel et al.[108] have used both ^{1}H- and ^{13}C-NMR to study the naphtha and light distillate saturated hydrocarbon fraction obtained from in situ shale oil. Both solid-state and high-resolution ^{1}H- and ^{13}C-NMR have been used to compare the hydrocarbon composition of shale oils produced by the pyrolysis and hydropyrolysis of Eastern and Western US oil shales.[109]

5 ANALYTICAL APPLICATION OF HIGH-RESOLUTION NUCLEAR MAGNETIC RESONANCE TO THE STUDY OF SHALE OIL FRACTIONS

NMR spectroscopy is an extremely useful technique for structural characterization of organic compounds and for quantitation of major functional groups in complex mixtures. The advantages of NMR spectroscopy are that it is nondestructive and the spectroscopic data can be reduced relatively easily to give the desired information. The technique is not as sensitive as MS and the application of the NMR to a mixture of similar organic compounds gives only the average structural properties of the molecular composition. As a result, the method is most useful for fractions in a narrow boiling range.

The chemical changes that occur when an oil shale is subjected to various physical and chemical treatments to yield shale oil can be followed using both liquid and solid-state NMR. Figure 10 shows the solid-state CP/MAS ^{13}C-NMR spectrum of a typical Colorado oil shale, and the spectra after the oil shale was (1) treated thermally to yield raw shale oil, (2) extracted with benzene before heating to yield shale oil bitumen, and (3) acid-treated to yield kerogen concentrate. One parameter which can easily be determined from each spectrum is the carbon

Figure 10 ^{13}C-NMR spectra of Colorado oil shale, kerogen, bitumen and shale oil.

aromaticity, f_a. This parameter is the fraction of aromatic carbons (aromatic integrated area) divided by the total number of carbons (sum of the aromatic and aliphatic integrated areas) measured in the NMR spectrum. The aromaticity values for this oil shale, shale oil, kerogen concentrate and bitumen were found to be 0.30, 0.295, 0.23 and 0.14, respectively.

To obtain additional average molecular structural information on the shale oil by NMR, the Hempel distillation method can be used to fractionate shale oil into naphtha, light distillate, heavy distillate and residue fractions. Figure 11 shows the high-resolution ^{13}C-NMR spectra for the different fractions from a Hempel distillation of an oil shale. Not only can the aromaticity value be measured for each fraction, but also other details about the average aliphatic structure can be obtained. These include the average carbon chain length of the alkane and relative percentages of normal and branched–cyclic alkanes. The naphtha and light distillate fractions can be further subdivided into saturates, olefins and aromatic subfractions by silica gel chromatography. A discussion of the NMR spectra of these subfractions follows.

5.1 Saturates

The ^{1}H-NMR spectra of the saturates from the naphtha and light distillate fractions of shale oil are shown in Figures 12(a) and 12(b), respectively. The resonance signals observed in the aliphatic region of the spectra are due to normal, branched and cyclic alkanes. Spectral assignments of the alkane hydrogens and the quantitative information which can be obtained have been discussed in the literature.[110–112] Table 7 lists the ^{1}H-NMR chemical shift values for the different hydrogen types. The interpretation of the ^{1}H-NMR spectra is straightforward. The resonance signals ranging from 0.5 to 1.0 ppm are due to terminal and branched methyl hydrogens. Methylene hydrogens in straight-chain or branched hydrocarbons have resonances in the range 1.2–1.3 ppm. The signal at 1.27 ppm in each spectrum is thus assigned to the methylene hydrogens. The intensity of this signal is primarily indicative of the alkane chain length. Cyclic methylene hydrogens range from 1.1 to 1.8 ppm. The shoulder at 1.34 ppm on the left of the straight-chain methylene hydrogens is assigned, in part, to these hydrogen types. Because of the overlap of the resonance signals of cyclic

Figure 11 ^{13}C-NMR spectra of fractions obtained from shale oil.

Table 7 ^{1}H- and ^{13}C-NMR chemical shift ranges

Definition	Chemical shift range (ppm from TMS[a])
^{1}H	
Monoaromatic hydrogens	6.6–7.2
Diaromatic hydrogens	7.2–7.8
Triaromatic hydrogens	7.8–8.3
Olefinic hydrogens	4.0–6.0
Methylene hydrogens alpha to aromatic ring	2.3–4.0
Methyl hydrogens alpha to aromatic ring	1.9–2.3
Naphthenic hydrogens beta to aromatic ring	1.6–1.9
β-CH_2– and β-CH_3 to aromatic ring and straight-chain alkane methylene hydrogens	1.0–1.6
γ-CH_3 to aromatic ring and straight-chain or branched alkane methyl hydrogens	0.5–1.0
^{13}C	
Total aromatic/olefinic carbons	100–150
Total aliphatic carbons	5–50
Methyl carbons of straight-chain alkanes	13.8–14.2
C_2-methylene carbons of straight-chain alkanes	22.7–23.0
C_3-methylene carbons of straight-chain alkanes	31.8–32.0
$C_{4,5,n}$-methylene carbons of straight-chain alkanes	29–30

[a] TMS, tetramethylsilane.

and straight-chain methylene hydrogens, the amount of quantitative information which can be extracted from these spectra is limited. However, area ratios of the methylene to methyl hydrogens were found to be 2.1 and 2.5 for the naphtha and light distillate saturates, respectively. Thus, semiqualitatively the naphtha saturates have on average shorter alkane chain lengths than the light distillate saturates. No evidence for aromatic (6–9 ppm) or olefinic (4–6 ppm) hydrogens can be found, indicating that the silica gel separation method is quite satisfactory for separating the saturates of the naphtha and light distillate fractions from other hydrogen types.

Figures 13(a) and 13(b) are ^{13}C-NMR spectra of the aliphatic region for the saturate cuts from the naphtha and light distillate fractions, respectively. The relatively few resonances shown in each spectrum suggest that the major constituent carbon types can be identified and quantified. The ^{13}C-NMR chemical shifts for the different carbon types are listed in Table 7. The following discussion refers to the ^{13}C-NMR spectrum of the light distillate saturate fraction (Figure 13b) but is also applicable to the interpretation of the ^{13}C-NMR spectrum of the naphtha saturate fraction. The five intense lines at 14.18, 22.88, 32.16, 29.62 and 29.95 ppm relative to TMS correspond to C-1, C-2, C-3, C-4 and C-5, respectively, of long-chain normal alkanes (see Figure 13b). However, neither the chemical shifts nor intensities correspond to any one *n*-alkane, since the spectrum is a composite of a distribution of several long-chain normal alkanes. The next set of resonances of medium intensity in the ^{13}C-NMR spectrum is due to symmetrically branched linear hydrocarbons having an isoprenoid-like structure. Phytane, pristane and others have all been identified in oil shale.[113] Figure 14(a) shows the identification of the signals with the corresponding carbon atoms in farnesane, a C_{15} isoprenoid.[114] The remaining signals in the ^{13}C-NMR spectrum of the light distillate saturates are due to unsymmetrically branched alkanes and cyclic alkanes. Some representative structures are shown in Figure 14(b).

The relative percentage of the combined branched and cyclic alkanes can be calculated by subtracting the area due to the *n*-alkanes from the total ^{13}C-NMR aliphatic carbon area. The ratio of the area of the branched and

Figure 13 ^{13}C-NMR spectra of the saturate cuts from (a) the naphtha and (b) the light distillate fractions.

Figure 14 ^{13}C-NMR spectral assignments for the saturate cuts from the light distillate fraction.

cyclic alkane carbons to the total aliphatic carbon area for the light distillate saturate fraction was found to be 0.31. Analytical results from a GC/MS determination on the same sample gave 73% *n*-alkanes, 20% branched alkanes, and 7% unidentified. The sum of the branched alkane and unidentified species content determined by GC/MS (27%) agrees reasonably well with the value found by ^{13}C-NMR (31%). A comparison of the MS and NMR percentage compositions for the saturate cuts from the naphtha and light distillate fractions is listed in Table 8. The data show that the NMR analysis of the saturates can give results comparable to GC/MS analysis.

Table 8 Comparison of the MS and NMR relative percentage compositions of saturate cuts from shale oil

	Naphtha fraction		Light distillate fraction	
	GC/MS	NMR	GC/MS	NMR
n-Alkanes	86	82	73	69
Branched alkanes	5		20	
Cycloalkanes	–	18	–	31
Unidentified	9		7	

5.2 Olefins

^{1}H-NMR can be used to analyze olefins in shale oil fractions. The proton spectra of the olefins obtained from the naphtha and light distillate fractions (Figures 15a and 15b respectively) show the presence of large amounts of methyl and methylene hydrogens and the presence of olefinic hydrogens at about 5.38 ppm relative to TMS. The ^{1}H-NMR olefinic region from 4 to 6 ppm has essentially no interference from hydrogens of other

Figure 15 ^{1}H-NMR spectra of the olefin cuts from (a) the naphtha and (b) the light distillate fractions.

Figure 16 ^{13}C-NMR spectra of the olefin cuts from (a) the naphtha and (b) the light distillate fractions.

types of functional groups. Thus, the olefin content can be measured quantitatively even for fractions with low olefin content. However, the position of the double bond in the alkene molecules cannot always be ascertained from the ^{1}H-NMR spectra but can from ^{13}C-NMR spectra.

The ^{13}C-NMR spectra (Figures 16a and 16b) of the olefin fractions of the shale oil naphtha and light distillation cuts can show clearly the position of the double bond for the different olefins. For the 1-ene olefin the carbons associated with the double bond are at 114 and 138 ppm. As the double bond moves along the carbon chain the differences between the chemical shifts of the two carbon atoms get smaller. For the 5-ene olefin, the carbon atoms associated with the double bond have nearly the same chemical shift. Thus, within the olefinic carbon region (114–138 ppm), it is possible to identify the most dominant double bond positions and determine their corresponding relative percentages. Table 9 lists the positions of the dominant olefinic bonds identified in the olefin subfractions of the naphtha and light distillate fractions. Also included in Table 9 are the observed chemical shifts of the olefinic carbons and the relative percentages. The double bond positions were identified by comparing the observed chemical shifts with those reported by Couperus et al.[115]

5.3 Aromatics

The ^{1}H-NMR spectra of the aromatic naphtha and aromatic light distillate fractions show considerable detail as to the types of protons present. In the naphtha fraction (Figure 17a), the ^{1}H-NMR spectrum shows evidence for the existence of small amounts of di- and triaromatic ring molecules (peaks with ^{1}H-NMR chemical shift values greater than 7.2 ppm). There is no evidence of these molecules in the light distillate fraction (Figure 17b) at the recorded signal-to-noise level. The relative amount of aromatic protons is also less in the light distillate than in the naphtha fraction (8.7% and 23.8%, respectively). In addition, the naphtha fraction has more α-CH_2 (42%) (CH_2 groups attached directly to an aromatic ring) than the light distillate fraction (26.6%). Thus, the ^{1}H-NMR data suggest the naphtha fraction contains mostly substituted monoaromatic compounds with apparently small amounts of di- and triaromatic molecules. The light distillate fraction is, on the other hand, composed mostly of monoaromatics which are less substituted, but the alkyl substituent is of longer carbon chain length.

Table 9 ^{13}C-NMR chemical shifts and relative percentages of normal olefins in naphtha and light distillate fractions obtained from shale oil

Double bond position (*n*-ene)	Naphtha fraction			Light distillate fraction		
	Chemical shift (ppm)		Relative percentage	Chemical shift (ppm)		Relative percentage

Figure 17 ^{1}H-NMR spectra of the aromatic cuts from (a) the naphtha and (b) the light distillate fractions.

Figure 18 ^{13}C-NMR spectra of the aromatic cuts from (a) the naphtha and (b) the light distillate fractions.

The ^{13}C-NMR spectra of the aromatics for both the naphtha and light distillate fraction (Figures 18a and 18b, respectively) show a large number of narrow and distinct resonances which, in principle, can be interpreted as to specific carbon type present. The naphtha fraction contains more aromatic carbons (greater aromaticity) relative to the light distillate fraction (54% and 32%, respectively). The corresponding relative amounts of

Table 10 Average molecular structural parameters for the aromatic subfraction obtained from the naphtha and light distillate fractions of shale oil

Average molecular structural parameters[116]	Equation[a]	Naphtha fraction	Light distillate fraction
Average number of aromatic carbons per molecule	$\#C_a = C_aMW/12$	8.5	5.3
Average number of saturate carbons per molecule	$\#C_s = A_2CMW/12$	7.2	11.5
Average number of substituents per molecule	$R_s = \%AS\#C_1/100$	4.0	3.3
Average number of carbon atoms per substituent	$n = (H_\alpha + H_\beta)/H_\alpha$	1.8	3.4
Average number of fused aromatic rings per molecule	$R_a = 1 + (\#C_a - \#C_1)/2$	0.6	0.6
Average number of nonbridged aromatic carbons per molecule	$\#C_1 = C_1MW/12$	9.4	6.1
Average number of saturate rings per molecule	$R_N = rR_s$	0.6	−1.0
Average number of saturate rings per substituent	$r = n + 0.5 - 6n/f$	0.2	−0.3
C/H weight ratio in alkyl groups	$f = A_2C/(H_\alpha + H_\beta)H$	5.0	4.9
C/H weight ratio in aromatic groups	$f_1 = A_1C/H_AH$	18.9	23.6
Fraction of carbons which are aromatic	$f_a = A_1/(A_1 + A_2)$	0.5	0.3
Weight fraction of sample which is aromatic carbon	$C_a = f_aC$	0.4	0.3
Weight fraction of sample which is nonbridged aromatic carbons	$C_1 = C_1^s + C_1^u$	0.5	0.3
Proportion of C_1 carbons which are alkyl-substituted	$C_1^s = A_2C/n$	0.2	0.2
Proportion of C_1 carbons which are unsubstituted	$C_1^u = 12H_AH$	0.3	0.1
Percentage substitution of nonbridged aromatics	$\%AS = 100C_1^s/C_1$	42.6	55.3

[a] Input data		Naphtha fraction	Light distillate fraction
A_1, A_2	= Normalized integrals for the aromatic (100–150 ppm) and alkyl (5–50 ppm) regions of the ^{13}C-NMR spectrum	0.540 0.460	0.317 0.684
H_A, H_α, H_β	= Normalized integrals for the aromatic (6.0–9.0 ppm), α-alkyl (2.0–4.0 ppm) and other alkyl (0.3–2.0 ppm) regions of the ^{1}H-NMR spectrum	0.238 0.420 0.341	0.087 0.266 0.647
C	= Weight fraction of carbon	0.792	0.819
H	= Weight fraction of hydrogen	0.091	0.126
MW	= Average molecular weight	238	246

aliphatic carbons were found to be 46% and 68% for the naphtha and light distillate fractions respectively.

A number of average molecular structural parameters[116] can be calculated for the aromatic subfraction of an oil. The underlying assumption is that the aliphatic carbons are attached to the aromatic molecule. Table 10 lists the definitions and equations for the structural parameters as well as the calculated values for the aromatic subfractions obtained from the naphtha and light distillate fractions from the Colorado shale oil. The data indicate that the average number of aromatic carbons per molecule in the naphtha fraction is 8.5 as compared with 5.3 in the light distillate fraction. The average numbers of saturate carbons per molecule are 7.2 and 11.5 and the average numbers of substituents per molecule are found to be 4.0 and 3.3 for the naphtha and light distillate fraction, respectively. The average carbon chain length per substituent for the naphtha and light distillate fractions is 1.8 and 3.4, respectively. From this information and additional data in Table 10, it appears that the naphtha fraction is highly substituted with short alkyl groups. The light distillate aromatic fraction on the other hand appears to have fewer substituents but longer carbon chain lengths per substituent. These conclusions are the same as the conclusions made from the ^{1}H-NMR spectra.

6 CONCLUSION

In 1973 there was a false belief that the world supply of petroleum was being rapidly depleted and by the year 2000 petroleum crude would be completely depleted. At this time a major emphasis was placed on the commercialization of oil shale conversion from which gasoline, diesel and jet fuels can readily be produced. Extensive research was conducted to develop more cost-effective retorting processes and analytical methodology to evaluate oil shale processes and shale oil products. However, since the early 1980s the petroleum supply has increased and the development of an oil shale industry has been limited by the commercial reality that petroleum

can be produced less expensively than shale oil. Until that time when petroleum becomes unavailable or too expensive, there will be little or no incentive to produce synthetic liquid fuels from oil shale on a large scale. How far into the future this will continue is difficult to predict.

Utilization of oil shale to replace petroleum will mean searching for economically efficient and environmentally acceptable recovery processes for the energy-rich organic material locked inside the oil shale's rock matrix. The recovery processes will involve a number of different kinds of technologies, including mining, size reduction, retorting or other means of recovering shale oil from the rock, disposal of the spent shale in an environmentally acceptable manner, and upgrading the shale oil into marketable products. On a commercial scale, to satisfy even a portion of the daily consumption of transportation fuels in the US, the amount of material that has to be mined and disposed of is staggering.

Because oil shales are diverse in their compositions, lithologies and genesis, their behavior during heating will also be different, as has been shown in preceding sections. Ongoing research continues at a low level. However, this has not led to new analytical methods to analyze oil shale and shale oil, so methods described in this article continue to be utilized.

Ethers and alcohols are being added to hydrocarbon fuels to produce the current generation of ''clean gasolines'' which are claimed to reduce air pollution. Also, alcohols provide a renewable energy source. However, the addition of oxygenates can change the volatility (as measured by the Reid vapor pressure) of a hydrocarbon mixture. This article reviews the equipment and measurement methods commonly used to study the vapor–liquid equilibrium (VLE) of hydrocarbon–oxygenate and gasoline–oxygenate mixtures. Detailed tables present those oxygenate–hydrocarbon mixtures for which VLE data are available.

1 INTRODUCTION

The development of ''clean gasolines'' in the United States has resulted in considerable interest in the measurement and correlation of VLE data for oxygenate–hydrocarbon mixtures. Of primary interest are ethers and alcohols and the effect of such added oxygenates on the volatility of gasolines. Gasoline volatility is generally reported as the Reid vapor pressure, that is, the pressure that would be produced when the gasoline is placed in an evacuated, closed container and partially vaporized as described by the American Society for Testing and Materials (ASTM) standard ASTM-D 323-94 Vapor Pressure of Petroleum Products (Reid Method). The Reid vapor pressure is an important characterizing parameter for gasoline, and there are United States Environmental Protection Agency (USEPA) limits on its value in commerce.

2 HISTORY AND ENVIRONMENTAL APPLICATIONS

Gasoline is neither a single identifiable component nor a well-defined mixture. Rather, it is a complex mixture of hydrocarbons largely in the boiling range of 40–200 °C. Gasoline is generally blended to produce a product with a desired antiknock or octane rating, little tendency to vapor lock (which depends on the vapor pressure of the fuel), and other specified properties. The composition of gasoline varies as a result of the starting crude oil, the producer, the season, the geographic location of use, the grade, and other factors. For many years tetraethyllead was used to increase the octane number of gasolines. This has been prohibited in many countries for environmental reasons, and also because lead is a poison to the catalytic converters now used on automobiles. Aromatics have high octane numbers, but recent restrictions on the amount allowed in gasoline have resulted in a further decrease in gasoline octane numbers. This has led to the increased use of nonlead octane enhancers. Oxygenates are octane-number enhancers, and several, especially methyl *tert*-butyl ether (MTBE) and ethanol, have been added to gasoline for this reason. Such blends have been referred to as ''clean gasolines''.

As the interest of refiners is to predict the effect of oxygenate addition on gasoline volatility, much of the VLE data are for the addition of an oxygenate to pure hydrocarbons or well-characterized mixtures of hydrocarbons. In particular, VLE data are available for mixtures of an oxygenate with either (1) a single hydrocarbon, (2) a mixture of defined hydrocarbons, or (3) a ''standard gasoline''. Such data are useful for determining parameters in activity coefficient or equation of state models that then allow gasoline refiners to make predictions for the behavior of their oxygenate–gasoline blends.

There are many oxygenates; however, this review with consider only ether- and alcohol-containing systems as only these oxygenates that have been widely used as gasoline additives. The most important data for

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

processing and for end-use in the clean gasolines is VLE, although other data such as liquid–liquid equilibrium (LLE) data are also of interest, especially because of the possibility of liquid–liquid phase splitting in the presence of water, or at high alcohol concentrations.

3 METHODS USED

There are two parts to determining the VLE of oxygenate–gasoline systems: one is producing VLE in the mixture, and the other is determining the composition of the equilibrium phases (although, as described below, in some experimental techniques the composition of one of the phases is gravimetrically prepared).

There are a number of ways that VLE data for mixtures can be obtained. The most complete data set includes the pressure (P), temperature (T), and the mole fraction compositions of the co-existing liquid (x) and vapor (y). Such data are referred to as $P–T–x–y$ data. For the correlation of such VLE data (especially for binary mixtures) it is preferable to have approximately 10 VLE points at each temperature covering the whole liquid composition range, together with the pure component vapor pressures measured in the same equipment. Usually, data for more than one isotherm would be reported. Data are also reported for a variety of compositions at a fixed pressure and therefore varying temperature. Such data are somewhat more difficult to correlate with thermodynamic models because of the temperature dependence of the model parameters, but are useful for distillation column design (as such devices operate close to isobarically), and generally are easier to measure using automated pressure control devices. Other types of VLE measurements include ebulliometry, static cell devices, gas–liquid chromatography (GLC), and headspace chromatography. As will be discussed below, each of these provides useful, but less complete, data in that either only a limited range of compositions are measured, or the compositions of one of the phases are not measured.

Recirculation equipment for VLE measurements has been discussed previously.[1,2] A double-recirculation still, one type of which is shown schematically in Figure 1, is frequently used to obtain $P–T–x–y$ data. [Note: there are many variations of this type of still, as can be seen in the literature.[1,2]] In the still shown, the liquid mixture boils in the still pot, producing a vapor–liquid mixture that is trapped in the inverted funnel region of a helical tube (a Cottrell pump), forcing the mixture into an adiabatic region where VLE is achieved. As the flow continues, the vapor and liquid phases disengage, the vapor is condensed, and the liquid and condensed vapor return

Figure 1 Schematic diagram of a double-recirculation VLE still: (1) still pot; (2) vacuum jacket; (3) Cottrell pump; (4) VLE chamber; (5) condensers; (6) injection ports; (7) filling spout and thermowell; (8) sample bypass valves; (9) sample tubes; (10) glass ball sampling valves; (11) thermowell; (12) platinum resistance thermometer; (13) solenoids to actuate sampling valves.

to the still pot by separate lines. Samples for analysis may be removed from the liquids in each of these lines. Depending on the mixture under study, different analytical methods can be used. For binary mixtures, techniques such as gas chromatography (GC) with an appropriate detector (see **Hyphenated Gas Chromatography**, **Column Technology in Gas Chromatography**, **Trace Organic Analysis by Gas Chromatography with Selective Detectors**), refractometry (for binary mixtures that are liquids under ambient conditions) and densimetry, have been used. For composition measurements involving real and simulated gasolines, which are multicomponent mixtures, GC is most commonly used.

The advantage of complete $P–T–x–y$ data for binary mixtures is that such data can be tested for thermodynamic consistency. However, such tests are not unambiguous. Also, composition measurements, especially of the condensed vapor, are the least accurate of the measurements made in VLE, and for some applications it is not necessary to have such complete data. Ebulliometry is one example of an experimental technique that results in useful, but less complete, data. In this technique, a gravimetrically prepared liquid sample is boiled in a still that recirculates the condensed liquid, and the temperature and pressure are measured. Figure 2 shows one example of such a device, though many variations exist. If the amount of recirculating liquid is not too large

Figure 2 Schematic diagram of an ebulliometer: (1) still pot; (2) Cottrell pump; (3) vacuum jacket and insulation; (4) VLE chamber; (5) thermowell; (6) thermocouple; (7) vapor passover line; (8) connection to pressure controller/vacuum pump; (9) coolant inlet and outlet; (10) condenser; (11) condensed vapor drop; (12) mixing chamber; (13) and (14) liquid recycle line; (15) stopcock; (16) drain port.

(so that the composition of the equilibrium liquid can be considered to be the same as the prepared liquid), one then obtains $P–T–x$ data, but not the composition of the co-existing vapor. Usually in such measurements, the pressure is fixed and the equilibrium temperature measured, since attempting to adjust the pressure might result in vaporization and loss of the more volatile component.

As the relative volatility of the components and/or the amount of condensed vapor holdup in the still increases, there is greater error in the assumption that the prepared and equilibrium compositions are identical. A common procedure is to correct for the liquid holdup using an iterative procedure; however, this requires knowledge of the amount of vapor holdup and the composition of the equilibrium condensed vapor, neither of which is known accurately. Consequently, this measurement technique is generally limited to relative volatilities (Equation 1):

$$\alpha_{ij} = \frac{y_i/x_i}{y_j/x_j} \tag{1}$$

of the two components in a binary mixture of between 0.1 to 10, as beyond this range the error from the unknown vapor phase composition becomes too large.

Ebulliometry is generally used for binary mixtures, and in either one of two ways. The first is by preparing gravimetrically a number of samples and obtaining $P–T–x$ data over the whole composition range. Barker's method[3] or its later variants is then used to calculate the vapor composition and then the activity coefficients. A simplified description of this calculation procedure is as follows. At low pressures, where the vapor phase can be assumed to be ideal, we have for species i at experimental point j that (Equation 2)

$$x_{i,j}\gamma_i(x_{i,j})P_i^{\text{vap}}(T) = y_{i,j}P_j \tag{2}$$

where $\gamma_i(x_{i,j})$ is the activity coefficient of species i at the mole fraction $x_{i,j}$ of that species at the jth experimental point at which the total pressure is P_j and $P_i^{\text{vap}}(T)$ is the vapor pressure of pure component i at the temperature T of the measurement. Summing over both species in a binary mixture at each experimental point gives Equation (3):

$$\sum_i x_{i,j}\gamma_i(x_{i,j})P_i^{\text{vap}}(T) = P_j \tag{3}$$

by assuming an activity coefficient model, for example, the very simple Van Laar model (see, for example, Sandler[4] for a discussion of various activity coefficient models), Equation (4):

$$\ln\gamma_1(x_{1,j}) = \frac{\alpha}{(1+\alpha x_{1,j}/\beta x_{2,j})^2}$$

and

$$\ln\gamma_2(x_{2,j}) = \frac{\beta}{(1+\beta x_{2,j}/\alpha x_{1,j})^2} \tag{4}$$

we have for the calculated pressure P_j^{calc} at each point (Equation 5):

$$x_{1,j}\exp\left[\frac{\alpha}{(1+\alpha x_{1,j}/\beta x_{2,j})^2}\right]P_1^{\text{vap}} + x_{2,j}\exp\left[\frac{\beta}{(1+\beta x_{2,j}/\alpha x_{1,j})^2}\right]P_2^{\text{vap}} = P_j^{\text{calc}} \tag{5}$$

Next, by using all the experimental data, one chooses the values of the adjustable parameters in the activity coefficient model (here α and β) to minimize the value of

an objective function F such as given in Equation (6):

$$F = \sum_{\substack{\text{experimental} \\ \text{points } j}} (P_j^{\text{calc}} - P_j^{\text{exp}})^2 \tag{6}$$

With the parameter values so obtained, the activity coefficient can be calculated at any composition. Then Equation (2) can be used to estimate the unmeasured vapor phase compositions. Note, however, that it is more common to use more sophisticated and somewhat more accurate activity coefficient models than the Van Laar model; also, more sophisticated parameter estimation methods, such as the maximum likelihood method,[5] can be used.

If the experimental data points are closely spaced, it is also possible to estimate the vapor compositions [and from those and Equation (2) the activity coefficients] without making any assumptions about the functional form of the activity coefficient model. Starting from the Gibbs–Duhem equation, and making the mild assumptions of an ideal vapor phase, and that $PV^{\text{ex}}/RT \ll 1$, where V^{ex} is the molar excess volume on mixing at constant temperature and pressure, one has (Equation 7)

$$x_1 \frac{\mathrm{d}\ln(x_1\gamma_1)}{\mathrm{d}x_1} + x_2 \frac{\mathrm{d}\ln(x_2\gamma_2)}{\mathrm{d}x_2} = 0 \tag{7}$$

which written on a point-by-point basis and using Equation (2) can be transformed into Equation (8):

$$\frac{(y_{1,j} - x_{1,j})}{y_{1,j}(1 - y_{1,j})} \frac{\mathrm{d}y_{1,j}}{\mathrm{d}x_{1,j}} = \frac{\mathrm{d}\ln P_j^{\text{exp}}}{\mathrm{d}x_{1,j}} \tag{8}$$

Replacing the derivatives by finite differences (which is why the experimental data must be closely spaced), and using the experimental pressure and liquid mole fractions and an appropriate numerical integration scheme, the value of the vapor-phase mole fraction can be computed for each liquid-phase mole fraction. This is called the synthetic method for obtaining P–T–x–y data using prepared liquid compositions without the direct measurement of the composition of either phase. This method is particularly useful in mixtures such as alcohols–hydrocarbons which exhibit very non-ideal behavior. For such systems most activity coefficient models cannot adequately represent the experimental data, particularly at low concentrations of the alcohol.[6]

The second method of using ebulliometry is to make a few measurements at the high-dilution range of each component, from these data to obtain the slope of the equilibrium temperature with composition at fixed pressure, and then calculate the infinite-dilution activity coefficient of each component in the other from Equation (9):

$$\gamma_i(x_i \to 0) = \gamma_i^{\infty} = \frac{P_j^{\text{vap}} - (\mathrm{d}P_j^{\text{vap}}/\mathrm{d}T)(\partial T/\partial x_i)_{T,x_i \to 0}}{P_i^{\text{vap}}} \tag{9}$$

Once the infinite-dilution activity coefficients have been obtained for each component in the other, their values can be used to obtain the parameters in a two-parameter activity coefficient model, and then to predict the VLE over the complete concentration range. Since ebulliometry is a dynamic boiling method using stills, similar to that used to obtain P–T–x–y data discussed above, it is of use for approximately the same relative volatility range.

To improve the accuracy of ebulliometric measurements, differential ebulliometry is commonly used. In this measurement method, two (or more) ebulliometers are connected to the same manifold, one containing the pure solvent as a reference and the other containing the solvent into which the solute is to be added. Then, by using differential thermometry, the temperature difference as a result of solute addition is measured directly. This is more accurate than using a single ebulliometer and measuring the two temperatures separately.

In static methods, boiling does not occur as it does in the dynamic methods discussed above. Rather, a cell is almost completely filled with a liquid of known (gravimetrically prepared) composition, closed, maintained at constant temperature, and the equilibrium pressure is measured. The advantage of such a cell is that very little of the liquid is vaporized, so except for the case of a very extreme difference in relative volatility, the error introduced by a changing liquid composition as a result of partial vaporization of the liquid is small. The disadvantage of such closed-cell equipment is that any gas dissolved in the liquid results in a significant error in the measured pressure. Therefore, the liquids have to be carefully degassed (by partial vaporization or alternate freezing, evacuation, and thawing) before introduction into the static cell. With this equipment, P–T–x data are generally obtained at constant temperature.

As in ebulliometry, measurements can be over the whole composition range, in which case the results are analyzed in the same manner as described above. Also, measurements can be made in just the high-dilution regions to obtain the slope of the equilibrium pressure with composition at fixed temperature. In this latter case the infinite-dilution activity coefficient of the solute in the solvent in a binary mixture is obtained from Equation (10):

$$\gamma_i(x_i \to 0) = \gamma_i^{\infty} = \frac{P_j^{\text{vap}} + (\partial P/\partial x_i)_{T,x_i \to 0}}{P_i^{\text{vap}}} \tag{10}$$

By obtaining both infinite-dilution activity coefficients, one can fit parameters to an activity coefficient model and estimate the VLE over the whole composition range.

Static cell methods have also been used to determine directly the effect on the Reid vapor pressure of the addition of an oxygenate to a real or simulated gasoline. In this case the oxygenate addition is done gravimetrically, so composition measurements are not required. The main difficulty is initial degassing the gasoline without changing its composition as a result of volatilization of the light components. Degassing of gasoline (or other mixtures) in such cases is generally done by placing the gasoline in the static cell, freezing to liquid nitrogen temperature, evacuating the headspace, thawing, and repeating the process a number of times until the vapor pressure remains constant on repeated cycles. In this way, dissolved gases such as oxygen and nitrogen can be eliminated without evaporation of the light hydrocarbon components.

The accuracy of the static cell measurements can be improved by using a differential method in which there are two (or more) static cells in the same temperature bath. The reference cell contains the pure solvent and the other cell contains solvent to which the oxygenate is to be added. A differential pressure transducer or similar device between the two cells directly measures the pressure difference resulting from addition of the oxygenate.

There also exist several gas–liquid chromatographic methods for determining infinite-dilution activity coefficients in a pure solvent. In each case the chromatographic column is loaded with the solvent and the solute is injected. By measuring the temperature, pressure, column loading, and the carrier gas retention volume, the infinite-dilution activity coefficient of the solute in the solvent can be calculated. Alternatively, by measuring only the temperature and the peak times for both a reference solute and the solute of interest, the ratio of their infinite-dilution activity coefficients in the solvent can be obtained.[7]

Headspace methods provide still another technique for obtaining VLE data. In this method, an equilibrium cell similar to a static cell is used. However, the liquids are not degassed prior to a measurement, and the total pressure generally is not measured. The headspace, that is, the vapor space above the liquid, is sampled and analyzed. Consequently, in this measurement method one obtains the equilibrium vapor composition in equilibrium with the prepared liquid. As with the other methods discussed, this technique can be used over the whole composition range, or only in the high-dilution regions to obtain infinite dilution activity coefficients.

LLE data are usually obtained using relatively simple, thermostated equilibrium cells to which the components are added and stirred to obtain equilibrium as shown in Figure 3. The stirring is stopped, time is allowed to let the phases separate, and then the equilibrium phases are sampled and analyzed. Care must be used on sampling not to contaminate one liquid phase with the other. The same methods of analysis as used for VLE can also be used for LLE. Liquid–liquid phase separation for the systems of interest here occurs when water is present, and in some alcohol–hydrocarbon systems.

Figure 3 Schematic diagram of an LLE cell.

4 GENERAL COMMENTS ON THE VAPOR–LIQUID EQUILIBRIUM OF OXYGENATE–HYDROCARBON SYSTEMS

As indicated in the tables that follow, there are many data sets for binary mixtures of oxygenates with hydrocarbons, for ternary mixtures of an oxygenate with two hydrocarbons or two oxygenates with a single hydrocarbon. There are relatively few published data for an oxygenate with a multicomponent hydrocarbon mixture or a gasoline. (Given the importance of such information in the fuels industry, it is likely such data have been measured but are proprietary.)

The VLE data show that ethers and hydrocarbons form nearly ideal mixtures. Consequently, the effect of the ether on the volatility (i.e. the Reid vapor pressure) of the gasoline–oxygenate mixture is largely determined by the vapor pressure of the oxygenate. It is partly for this reason that largely C_5 and higher carbon number ethers have been used as gasoline additives. MTBE is the oxygenate most commonly used in the USA, and may

result in a very slight increase in the Reid vapor pressure of a gasoline. Higher ethers such as *tert*-amyl methyl ether (TAME), diisopropyl ether (DIPE), and others, which are less volatile, have little effect on the Reid vapor pressure of the gasoline at the concentrations in which they are used, and may even result in a slight lowering. One method of lowering the Reid vapor pressure of a gasoline is to reduce its content of C_4 hydrocarbons, which has resulted in a refinery stream that can be converted to MTBE. As a result, MTBE is relatively inexpensive and the mostly widely used oxygenated gasoline additive. However, there are concerns about the environmental effects of MTBE, particularly with regard to groundwater contamination.

Alcohols form nonideal mixtures with hydrocarbons. These mixtures show positive deviations from Raoult's law; consequently, if a low-molecular-weight alcohol such as methanol or ethanol is added to gasoline, an increase in the Reid vapor pressure will result. Also, some alcohol–gasoline mixtures, particularly those containing methanol, exhibit liquid–liquid phase splitting. Many binary mixtures of an alcohol and a hydrocarbon have a minimum boiling azeotrope and/or liquid–liquid partial immiscibility. Ethanol is the alcohol most commonly used as a gasoline additive as a result of its availability from renewable or surplus agricultural products, and its low cost. Since ethanol is available domestically, it can be used to reduce a country's dependence on foreign crude oil. Indeed, it has been used in this manner at concentrations exceeding 20 wt% in Brazil. Methanol has been used as a gasoline replacement.

There has been some interest in the VLE of gasoline with mixed oxygenates, especially an ether and an alcohol. Some of the data sets given in the tables reflect that interest.

5 REVIEW OF MEASUREMENTS OF THE VAPOR–LIQUID EQUILIBRIUM OF OXYGENATE–HYDROCARBON SYSTEMS

This review of measurements only covers mixtures of ethers or alcohols with hydrocarbons. Most of the data that have been reported are for binary mixtures, although ternary and multicomponent mixtures are also considered. The properties reviewed are VLE and LLE. The literature search was made using on-line and hard-copy versions of *Chemical Abstracts*, on-line *Current Contents*, various Thermodynamics Research Center electronic databases,[8] the EVLM'97 electronic database,[9] the Dortmund Data Bank,[10,11] and recent volumes of *Fluid Phase Equilibria*, *Journal of Chemical Thermodynamics* and *Journal of Chemical and Engineering Data*.

In the tables, a tick indicates that one or more measurements have been made on a particular system. Table 1 indicates measurements made on MTBE, TAME, diethyl ether (DEE), and butyl methyl ether (BME) with hydrocarbons and with other ethers. Table 2 contains information for measurements made on mixtures of dipropyl ether (DPE), ethyl *tert*-butyl ether (ETBE), dibutyl ether (DBE), and diisobutyl ether (DIBE) with hydrocarbons and other ethers. Table 3 contains information on binary mixtures of methanol and ethanol with hydrocarbons–ethers. Table 4 shows the measurements made on multicomponent mixtures containing ethers–hydrocarbons–other components and Table 5 indicates measurements available on multicomponent mixtures containing alcohols–hydrocarbons–other components. Complete annotated references to the measurements on ethers are given in a recent review.[12]

6 DISCUSSION

The experimental methods used to obtain VLE data in oxygenate–hydrocarbon and oxygenate–gasoline systems are well established, and provide no unusual challenges. Consequently, many data are available. There are a considerable number of VLE data sets for alkanes and cycloalkanes up to C_8 for mixtures with ethers. There are few measurements on alkanes larger than C_8. There are a large number of VLE measurements for mixtures of MTBE with alkenes, but none with alkynes. For aromatic compounds there exists a comprehensive

set of VLE measurements, except for ethylbenzene and propylbenzene. There are VLE data for MTBE with various synthetic gasoline blends, and there have been a considerable number of measurements reported for MTBE–alkanes + a third component including alkanes, cycloalkanes, aromatics, ethers, and alcohols. Studies on ternary mixtures with cycloalkanes have been restricted to cyclohexane, while benzene has been the main aromatic compound studied. There is a general lack of LLE data for ternary systems involving alcohols or water.

There are no VLE measurements of TAME with hexane and alkanes larger than C_8 and limited measurements with the branched alkanes. There are sufficient VLE measurements for modeling purposes with the alkenes, though not as extensive as for MTBE, but there are no VLE measurements with the alkynes. Considerably fewer measurements have been reported for ternary mixtures containing TAME than for MTBE. While the measurements cover a cross-section of the classes of mixtures, more measurements are warranted, especially on systems containing TAME–aromatic–water, TAME–aromatic–alcohol, TAME–alkene–water, and TAME–alkene–alcohol.

There exist VLE measurements for binary mixtures with dimethyl ether (DME), DEE, and BME and a good selection of hydrocarbons.There are no measurements for DPE with alkenes, while for some mixtures, e.g. DIPE separately with heptane, cyclohexane, and benzene, many VLE data sets have been reported. There are adequate measurements on binary mixtures with ETBE and DBE, but virtually no measurements with DIBE. There have been few measurements on ternary mixtures containing ethers other than MTBE and TAME. Additional measurement should focus on the LLE for mixtures containing ethers–hydrocarbons–alcohols and ethers–hydrocarbons–water.

For binary mixtures of either methanol and ethanol with mixtures of a wide range of hydrocarbons there are many measurements of both VLE and LLE (where applicable), and there appears to be little need for any additional measurements. There are many measurements

of LLE for mixtures of alcohols–hydrocarbons–water, but there are a limited number of VLE data for such ternary mixtures. As noted, there are few data for alcohols–ethers–hydrocarbons. There are limited data for ternary alcohol–hydrocarbon–hydrocarbon mixtures and more measurements are warranted.

The three IUPAC Workshops on Vapor–Liquid Equilibria and Related Properties in Binary and Ternary Mixtures of Ethers, Alkanes, and Alkanols have stimulated much of the recent experimental work. There is now a very adequate database on VLE and LLE for many mixtures containing ethers.

ACKNOWLEDGMENTS

We wish to acknowledge the extremely valuable help of Professor J. Gmehling of the Universität Oldenburg in providing the information that allowed us to assemble the tables presented here, and to Prin Naimskul of the University of Canterbury for his help. Also, S.I.S. would like to acknowledge the financial support of the US National Science Foundation provided through grant number CTS-9521406

Petroleum residues are the remaining fraction left after the distillation of crude oil. According to the conditions of the primary distillation, a distinction is made between atmospheric and vacuum residues (VRs). Since the simplest, lighter constituents of petroleum have been separated by distillation, residues constitute the most complex fraction of crude oil and a detailed inventory of the individual compounds is impossible. Thus characterization methods will aim at giving an adequate description of the pertinent properties for a given purpose. Practically all of the existing analytical techniques have been applied: chromatographic, spectroscopic, solvent extraction, fractionation, etc. The analyst's strategy will consist in choosing the procedure that will be able to provide limited but pertinent information, at an acceptable cost, in a reasonable time. Some easily obtained physical parameters correlate with chemical composition data. This is the case with specific gravity, viscosity, and the content of carbon residue obtained after pyrolysis. Standard test methods for the determination of these parameters have been developed.

The direct determination of compositional parameters such as aromatic carbon and hydrogen content is obtainable through nuclear magnetic resonance (NMR) spectroscopy without previous fractionation. The quantitative distribution of saturated, aromatic, and polar compounds can be measured by thin-layer chromatography (TLC) coupled with flame ionization detection (FID). The parameters obtained through various analytical techniques are generally hardly correlated since they refer to different units (e.g. mole %, weight %, or volume %) that cannot be interconverted.

A more detailed characterization requires previous separation for the preparation of simpler fractions. Although the definition of residues implies they have been produced after a preliminary distillation, short-path molecular distillation, simulated distillation by high-temperature gas chromatography (GC), and supercritical fluid extraction (SFE) apply to residues and provide the distribution of fractions possessing equivalent boiling point up to about 720°C at atmospheric pressure. The fractions resulting from distillation cuts can subsequently be characterized. Simulated distillation by GC can be coupled with other analytical tools such as element-specific detectors or a mass spectrometer.

The separation of components in residues can be performed according to their solubility in solvents possessing increasing polarity or by chromatographic solvent elution after preliminary adsorption of the dissolved sample on a solid adsorbent. Among a wide variety of separation schemes, some have been standardized and the corresponding fractions are designated according to solubility: oils or maltenes, resins, and asphaltenes. The yield of the fractions is indicative of composition and behavior during further processing of residues.

Further characterization of fractions involves either chromatographic or spectroscopic techniques. Chromatographic methods include thin-layer, liquid-phase, and

R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

size-exclusion modes and provide information related with composition of fractions in terms of hydrocarbon group types (saturated, aromatics, polars) and molecular weight distribution. Spectroscopic methods [ultraviolet (UV), mass, NMR] are suitable for compositional evaluation.

Physical and analytical parameters can be correlated with the distribution of structural groups existing in the hydrocarbon fraction of residues: paraffinic, naphthenic, olefinic, and aromatic (single or fused rings).

1 INTRODUCTION

Fossil fuels, excluding natural gas, represent a challenge for the analytical chemist. The molecules that they contain range from light hydrocarbons to extremely complex macromolecular structures which are the memory or fingerprints of living matter origin. The complexity originates from the process of biological material decomposition and further maturation, which are responsible for the genesis of petroleum. Considered as a global degradation, this process would give rise to the formation of a limited range of products, but, simultaneously, reactive intermediates generated during the course of degradation may recombine or associate, giving rise to the production of new entities which may exhibit a higher degree of complexity than the corresponding fragments. Prior to further processing, crude oil is first subjected to atmospheric or reduced pressure distillation; this separation yields a distillate fraction – commercialized, after adequate treatment, as gasoline, kerosene, fuel oil, etc. – and a residue. Since the simplest, lighter constituents of petroleum have been separated by distillation, residues constitute the most complex fraction of crude oil.

Owing to the associated and micellar nature of residues, an exhaustive inventory of individual components is definitively beyond reach. Hence characterization methods will aim at giving an adequate description of the pertinent properties for a given purpose. Practically all of the existing analytical techniques have been applied, but the main, hardly solvable, problem is the intercorrelation of data obtained from distinct methods. Thus, rather than pursuing a hypothetical universal method, the analyst's strategy will consist in choosing the procedure that will be able to provide limited but pertinent information, at an acceptable cost, in a limited time.

Some easily obtained physical parameters correlate with chemical composition data. This is the case with specific gravity, viscosity, and the content of carbon residues obtained after pyrolysis. Standard test methods for the determination of these parameters have been developed.

The direct determination of compositional parameters such as aromatic carbon and hydrogen content is obtainable through NMR spectroscopy without previous fractionation. The quantitative distribution of saturated, aromatic, and polar compounds can be measured by TLC coupled with FID. The parameters obtained through various analytical techniques are generally hardly correlated since they refer to different units (e.g. mole %, weight %, or volume %) that cannot be interconverted.

A more detailed characterization requires previous separation for the preparation of simpler fractions. Although the definition of residues implies they have been produced after a preliminary distillation, short-path molecular distillation, simulated distillation by high-temperature GC and SFE apply to residues and provide the distribution of fractions possessing equivalent boiling points up to about 720 °C at atmospheric pressure. The fractions resulting from distillation cuts can subsequently be characterized. Simulated distillation by gas chromatography (Simdist GC) can be coupled with other analytical tools such as an element-specific detector or a mass spectrometer.

The separation of components in residues can be performed according to their solubility in solvents possessing increasing polarity or by chromatographic solvent elution after preliminary adsorption of the dissolved sample on a solid adsorbent. Among a wide variety of separation schemes, some have been standardized and the corresponding fractions are designated according to solubility: oils or maltenes, resins, and asphaltenes. The yield of the fractions is indicative of composition and behavior during further processing of residues.

Practically all currently practised analytical techniques are applied to the further characterization of fractions. Chromatographic methods include thin-layer, liquid-phase, and size-exclusion modes and provide information related to the composition of fractions in terms of hydrocarbon group types (saturated, aromatics, polars) and molecular weight distribution. Spectroscopic methods (UV, mass, NMR) are suitable for compositional evaluation.

Physical and analytical parameters can be correlated with the distribution of structural groups existing in the hydrocarbon fraction of residues: paraffinic, naphthenic, olefinic, and aromatic (single or fused rings).

2 COMPOSITION OF PETROLEUM

2.1 Definition of Residues

Petroleum is a mixture of liquid, solid, and gaseous hydrocarbons and other minor components, whose composition is extremely variable according to the origin of the sedimentary deposits from where it is extracted; variability in composition is also observed within a given oilfield. The hydrocarbon components of petroleum can be separated

into distinct products by atmospheric pressure distillation. The nondistillable fraction is named the atmospheric residue. The distillation end-point affects the properties of the resulting residue. The practical limit for atmospheric pressure distillation is about 360 °C, since thermal decomposition occurs at higher temperatures. During petroleum refining, the atmospheric residue is usually submitted to low-pressure distillation, yielding a distillate (vacuum gas oil) and a VR. The atmospheric pressure equivalent temperature of vacuum distillation is about 560 °C.

Residues are black, viscous material, liquid or almost solid at room temperature. The specific gravity varies from 0.95 to 1.02 and the pour point ranges between 10 and 50 °C. The yield of residue obtained from crude oil distillation is extremely variable: light oils produce as low as 10% VR, whereas some heavy oils can yield up to 70% VR. The major part of proven world petroleum reserves is composed of heavy oils and tar sand deposits. The progressive introduction of these new resources in refineries will cause an increase of the portion of residues generated by primary distillation, while the demand for light products tends to grow. As a consequence of this conflictive evolution of offer and demand, processes dealing with conversion of residues for the production of more valuable products such as transportation fuels will acquire increasing importance. In this context, a precise evaluation of the properties of residues in relation to processability will be required.

2.2 Constituents

The complexity of petroleum residues is related to the mechanisms of petroleum genesis. Crude oil is the product of decomposition of plant and animal debris in a marine environment, incorporated in sediments. Some of the constituents are directly correlated with living matter origin:

- paraffinic, naphthenic, terpene, and carotene hydrocarbons are widely distributed in living plants;
- the decarboxylation of fatty acids yields hydrocarbons;
- porphyrins (Ni or V complex of porphine derivatives) are considered as degradation products of chlorophyll and pigments.

Figure 1 Definition of the major components obtained from residue fractionation.

Since the simplest, lighter constituents of petroleum have been separated by distillation, residues constitute the most complex fraction of crude oil. Attempts to fractionate residues further have been conducted since the early stages of petroleum science. As a general trend, extraction with solvents of increasing polarity provides fractions of increasing molecular weight and/or aromaticity. Solvent-extraction protocols have been developed on an empirical basis and a complex, confusing nomenclature has been derived. Some of the representative fractions obtained by solvent extraction are illustrated in Figure 1. The fraction that is soluble in light paraffins is named maltenes. Further fractionation of maltenes yields oils and resins (extracted with benzene). Asphaltenes, insoluble in paraffins, are soluble in benzene; the remaining insoluble fraction is named carbenes, which are further fractionated into carboids (insoluble in pyridine). The yield of the defined fractions is dependent on the operating conditions: nature of the paraffinic solvent, concentration, temperature. These components are far from representative of a chemical class and their elemental composition is extremely variable (Table 1). Based on the constituents derived from fractionation, petroleum residues may conceptually be visualized as a micellar suspension of asphaltenes and resins within a continuous oily phase. The distribution of the three main components (oil, resins, and asphaltenes) may be related to maturation of petroleum, and some correlations between reservoir characteristics and composition of crude oil have been observed.

Table 1 Yield and range of variation of selected properties of oils, resins and asphaltenes obtained from residues fractionation

Fraction	Yield (%)	Molecular weight	Atomic ratios			
			H/C	N/C	O/C	S/C
Oils	45–60	300–600	1.5–2	0	0	0.001–0.03
Resins	20–40	700–1000	1.3–1.7	0.002–0.008	0.002–0.05	0.003–0.04
Asphaltenes	10–30	2000–10 000	0.9–1.3	0.005–0.03	0.005–0.04	0.001–0.04

3 DETERMINATION OF SOME PHYSICAL PARAMETERS OF RESIDUES

As a raw material destined to yield secondary products, residues are generally subjected to further processing. According to compositional properties such as sulfur, asphaltene, or metal content, some types of residues may possess some economic benefit as a source of fuel, as a feedstock for cracking, or for any given purpose. Others may contain exceedingly low concentrations of oily components for the manufacture of lubricating oil, for instance, that may not be economically acceptable. It is therefore necessary to perform the selection of this raw material on the basis of the subsequent end product.

In view of the extreme complexity of petroleum, in-depth analytical evaluation of residues is an exceedingly difficult task. However, recourse to sophisticated analytical techniques is not necessary for obtaining the relevant properties related to a given use. This is the case with some easily obtained physical parameters that correlate with chemical composition data: specific gravity, viscosity, Conradson carbon, refractive index. Methods for the determination of essential parameters have been standardized by major standards organizations, and test methods have been developed and published by the American Society for Testing and Materials (ASTM), 100 Barr Harbor Drive, West Conshohocken, PA 19428-2959, USA.

3.1 Specific Gravity

It was early recognized that density (relative to water) or specific gravity (sp gr expressed in $g\,cm^{-3}$) is roughly correlated with the expected yield of distillate obtainable from crude oil. Determination can be performed by means of a pycnometer or hydrometer. It is generally expressed as American Petroleum Institute (API) gravity, defined according to Equation (1):

$$\text{degree API} = \frac{141.5}{\text{sp gr at } 15\,^{\circ}\text{C}} - 131.5 \qquad (1)$$

Since residues are highly viscous at 15 °C, the determination may be performed at higher temperature and a correction for thermal expansion applied (ASTM D1217 and D1555).

Automated apparatus (ASTM D5002) for the determination of density are based upon the change in oscillating frequency of a cell containing the liquid to be evaluated, as compared with a reference liquid (generally water). Density is proportional to the square of the variation of oscillation frequency. It is expressed as Equation (2):

$$d_S = d_W + K(T_S^2 - T_W^2) \qquad (2)$$

where d_S is the density of the sample, d_W is the density of water at the temperature of measurement, K is an instrumental constant, and T_S and T_W are the period of vibration for the sample and for water, respectively. Provided that the temperature is controlled at $\pm 0.1\,^{\circ}C$, the observed reproducibility of determination with heavy samples such as residues is better than $0.005\,g\,cm^{-3}$.

This very straightforward, easily obtained property is correlated with sulfur, nitrogen, and asphaltenes content and Conradson carbon residue; as a general trend, higher heteroatoms and asphaltenes content result in increased specific gravity.

3.2 Viscosity

Similarly to density, viscosity is of considerable practical importance for the petroleum industry since it is directly related to the flow characteristics of oil. Viscosity is usually expressed in centipoise ($1\,cP = 10^{-3}\,Pa\,s$) and kinematic viscosity, which relates viscosity to specific gravity, is expressed in centistokes ($1\,cSt = 10^{-6}\,m^2\,s^{-1}$). The viscosity of residues ranges between 10^3 and 10^7 St.

The determination is based either on capillary instruments applying the Poiseuille equation and giving a direct measure of viscosity, or on calibrated orifice devices as the measure of flow time (t). Depending on the orifice geometry, several test methods are used and the corresponding scales of viscosity can be converted to kinematic viscosity (v) by applying the empirical Equation (3):

$$v = At + \frac{B}{t} \qquad (3)$$

Numerical values of A and B are given in Table 2 for commonly used viscosity scales. The variation of viscosity with temperature (viscosity index, ASTM D2270) is an important expression for the use of the oily fraction of residues as a basis for the elaboration of lubricating oils. It is related to compositional characteristics of residues since it has been observed that, at comparable viscosity, naphthenic oils have a higher viscosity index than paraffinic oils.

3.3 Carbon Residue

This parameter is a measure of the amount of carbonaceous residue left after pyrolysis under on inert gas above 500 °C. It is useful to characterize the depositing propensity of residual fuels used in burning equipment

Table 2 Coefficients for conversion of viscosity scales

Scale	A	B
Saybolt	0.0022	1.8
Redwood	0.0026	1.72
Engler	0.00147	3.74

or internal combustion engines. According to the test method, the numerical value is named Conradson carbon (ASTM D189), microcarbon residue (ASTM D4530) or Ramsbottom carbon (ASTM D524). Owing to the empirical character of the determination, data obtained from these methods are not strictly equivalent but can be interconnected.

Interesting relationships have been observed between Conradson carbon residue and compositional characteristics. Residual carbon is proportional to sulfur, nitrogen, and asphaltenes content. An inverse correlation is observed between carbon residue and hydrogen-to-carbon ratio.

4 CHEMICAL ANALYSIS WITHOUT PREVIOUS FRACTIONATION

4.1 Elemental Analysis

Generic methods for elemental analysis are generally applicable for residue evaluation. However, the commercial importance of fuel characterization has justified manufacturers developing dedicated instruments. The specifications and range of application of commercial equipment generally exceed the requirements of current standard test methods.

Carbon content is determined through combustion in oxygen and measurement of the evolved CO_2. Proper control of the combustion is of critical importance for precision. It includes the use of catalytically additive, programmed sequences of previous pyrolysis and combustion, and programmed temperature ramps, which are generally proprietary. Water produced during combustion is absorbed by magnesium perchlorate. According to the instrument design, the CO_2 produced may be determined gravimetrically after absorption in sodium hydroxide deposited on an inert support; alternatively, the content of CO_2 in the collected combustion gases can be determined by infrared (IR) absorption measurement.

Hydrogen content can be obtained simultaneously along with carbon determination by gravimetry of the absorbed water formed during combustion of the sample. Specific low-resolution NMR-based methods (ASTM D4808) have been developed for the measurement of total hydrogen in residues and good correlation is obtained between NMR data and combustion data. Provided that the specific gravity of the sample is previously determined with good accuracy, the routine NMR determination of total hydrogen content does not require weighing of the sample.

Nitrogen determination involves a previous combustion of the sample. According to the type of instrument, elemental nitrogen remaining after combustion is quantified by a thermal conductivity detector, after water and CO_2 have been absorbed and eliminated from the combustion gases. Alternatively, nitrogen may be catalytically oxidized during combustion to nitric oxide (NO); further reaction of the combustion gases with ozone produces excited nitrogen dioxide, which is quantified with a chemiluminescent detector.

Sulfur content determination is generally performed through combustion and further evaluation of the sulfur dioxide produced in the combustion gases. Distinct methods for SO_2 detection are implemented in commercial equipment: simultaneous determination of carbon and sulfur can be performed by IR absorption measurement; alternatively, UV fluorescence of SO_2 is employed in some types of apparatus; another option consists in the absorption of SO_2 in iodide solution followed by coulometric measurement of the iodine produced. This method possesses the distinct advantage that it is an absolute determination that does not require calibration with standards. The range of concentration attainable by both techniques greatly exceeds the sulfur content usually found in residues; the detection limit (DL) may be as low as 100 ppb while the maximum concentration is about 5%. Higher contents can be determined after previous dilution of the sample.

Energy-dispersive X-ray fluorescence (EDXRF) is currently the most popular method for sulfur determination in many petroleum-based matrices since it does not require special skill, and measurement is fully automated. However, caution must be exercised for its application to residues since the samples are generally too viscous to be poured directly into the analytical cells. Special cells, designed for handling pastry materials, may circumvent this difficulty. Dilution of the analyte with a solvent may cause some flocculation which affects the stability of measurement. This drawback may be partly resolved by a sample spinning device incorporated in some instruments.

Metal content (mainly nickel and vanadium) determination is easily performed by EDXRF. The state of the sample is also critical: homogeneity for diluted liquid samples must be preserved, and solid-state samples require a previous preparation of the exposed surface for obtaining reliable results. The elaboration of solid-state standards requires special skill. The determination of metal content can be performed by inductively coupled plasma atomic emission spectroscopy (ICPAES). It requires the previous dissolution of the sample, hence incomplete solubility may cause some errors due to segregation or flocculation of carboid fractions.

4.2 Evaluation Without Previous Fractionation

Analytical techniques to be used for the characterization of residues must be fast, (i.e. applicable without previous fractionation), repeatable, and quantitative. They must

also provide information regarding the distribution of chemical families, alternatively referred to as hydrocarbon group type analysis (HGTA). A rigorous analysis of residues typically involves at least one chromatographic separation step during sample preparation, which is followed by consecutive characterization of the fractions. These fractionation steps are lengthy and tedious, hence many attempts have been made to obtain information related to composition in terms of distribution of saturated, aromatic, or polar compounds, without previous fractionation. Some techniques may provide HGTA data without any previous separation. This is the case with TLC and or ^{13}C-NMR spectroscopy.

Repeatability of analytical techniques is generally considered as a criterion for protocol selection, along with reliable quantitative determination. It must be pointed out that, in the absence of detailed information concerning individual constituents of complex mixtures, quantitation is related to internal consistency. Effectively, the definition of the considered hydrocarbon groups is often ambiguous; for example, if aromatic and saturated hydrocarbons are distinguished by a given analytical method, the distribution of hydroaromatic species between these two classes will depend on the chosen protocol. Hence internal consistency does not imply the exactness of data, and comparisons with additional analytical techniques must be made in order to assess the meaningfulness of one particular technique.

Another kind of difficulty arises from tentative comparisons of data obtained with distinct tools. It comes from the fact that the results provided by different analytical techniques are expressed in distinct units: some are expressed on a weight basis, others on a molar basis. Direct comparison of the results are meaningless, since unit conversion relies upon some external hypothesis concerning the composition of the analyte. Therefore, although analytical data are inter-related, the correlation between two distinct techniques relies upon a third external data or upon some hypothesis concerning the molecular structure.

^{13}C- and ^{1}H-NMR are the methods of choice for aromatic carbon and aromatic hydrogen content determination (ASTM D5292). Samples need previous homogenization before dissolution in deuterated chloroform or in a mixture of carbon disulfide and deuterated chloroform. The aromatic hydrogen content (weight %) is measured by comparing the integrals of the signals in the ^{1}H-NMR spectrum between 5.0 and 10.0 ppm for aromatic hydrogen and between -0.5 and 5.0 ppm for aliphatic hydrogen. Similarly, the aromatic carbon content (weight %) is measured by comparing the integral of the signal in the ^{13}C-NMR spectra between 100 and 170 ppm for aromatic carbon and -10 and 70 ppm for aliphatic carbon, after correction for the aliphatic fraction of reference material. DLs are typically 0.1 mol% aromatic hydrogen atoms and 0.5 mol% aromatic carbon atoms. The olefin and phenol content must be below 1%.

Chromatographic techniques allow the separation and quantitation of hydrocarbon groups, after an adequate calibration procedure. High-performance liquid chromatography (HPLC) is not directly applicable to residues owing to the possible irreversible adsorption of heavy and/or polar compounds on the columns and, hence, incomplete elution.

TLC has long been applied to the separation of complex materials. It requires very simple equipment but cannot provide quantitative information. A substantial improvement of TLC has been accomplished by coupling with quantitative FID. Instead of performing the chromatographic separation on glass plates covered with a layer of porous medium, generally alumina, the sample is deposited on silica rods about 1 mm in diameter and 10 cm long, coated with a separation medium. After elution with solvents, the rods are scanned over the flame of the detector, which provides a quantitative signal. Hence this technique grants the possibility of quantifying the uneluted heavy and polar products, in addition to increasing the speed of the analysis. Hydrocarbon groups are classified according to elution sequences with selected solvent systems, a practice which allows the determination of saturated, alkylaromatic, aromatic, and polar compounds. A typical separation of a residual oil is illustrated in Figure 2.

As with other chromatographic methods, quantitative results are based upon absolute calibration, which requires a previous preparative chromatographic step in order to obtain external standards. However, a rapid

Figure 2 Separation of a residual oil by TLC/FID using a consecutive sequence of elution with *n*-hexane, toluene, and dichloromethane–methanol (95 : 5 v/v). (Reproduced from the *Journal of Chromatographic Science* by permission of Preston Publications, a Division of Preston Industries, Inc.)

internal calibration procedure has been developed.[1] Results are obtained on a weight % basis.

Small-angle X-ray scattering has been applied to the determination of the mean molecular weight of residues, since this parameter is related to the radius of gyration obtained from diffused intensity for diffusion angles smaller than 4° (2θ). This technique provides good agreement with molecular-weight data for asphaltene fractions obtained by gel permeation chromatography (GPC). In the case of raw and hydrotreated residues, polydispersity is evidenced.[2]

5 FRACTIONATION

The purpose of fractionation is the production of a significant amount of different fractions of the residue for further characterization. The composition of the fractions is supposedly simpler than that of the whole sample, thus allowing more specific analytical techniques to be applied. Owing to the extreme complexity of residues, it is clear that an infinite variety of fractionation schemes can be imagined and that the definition and properties of the resulting fractions will depend strongly on the applied procedure. The general goal is to obtain a classification based upon some difference in chemical properties. However, the presence of many multifunctional compounds and the wide distribution of molecular weights are the cause of overlapping of fractions. Hence, owing to the impossibility of defining an absolute scheme of separation, reproducibility must be considered as the only pertinent criterion. As a consequence, the standardization of fractionation protocols is of primary importance, although they are partly based upon empirical practice.

5.1 Solvent Extraction

Numerous separation schemes have been developed for the preparation of fractions from residues. Some proposed fractionations are illustrated in Figure 3(a) and (b). No standard methods have been elaborated. The only exception concerns the precipitation of asphaltenes with *n*-heptane (ASTM D3279). The properties of the generic fractions (asphaltenes, maltenes, resins, wax, and oils) are obviously dependent upon the chosen solvent sequence. For instance, the yield and properties of precipitated asphaltenes vary with the number of carbon atoms in the paraffinic solvent, temperature, relative volume of solvent, and contact time.[3] Consequently, the terminology of the fractions obtained cannot be considered as representative of a class of compounds. The positive aspect of solvent fractionation is the complete recovery of material without loss through irreversible adsorption, as occurs in chromatographic separation techniques. The use of large volumes of solvents and the tedious, lengthy character of the separation procedure advocate the use of alternative methods.

Figure 3 Two solvent fractionation schemes. (Reprinted from J.G. Speight, *The Chemistry and Technology of Petroleum*, Marcel Dekker, New York, 327–328, 1991, by courtesy of Marcel Dekker Inc.)

5.2 Adsorption Chromatography

Chromatographic procedures involve the previous adsorption of a solution of residue on a solid adsorbent. Consecutive elution with solvents yields fractions, characterized by the polarity of the corresponding elution solvent. Since asphaltenes are irreversibly adsorbed, prior separation must be considered, applying a standard

Figure 4 The USBM/API separation procedure.

method. The textural and surface properties of the solid adsorbent directly influence the separation process, hence reproducibility of the solid phase must be guaranteed for the credibility of the analytical method.

The United States Bureau of Mines/American Petroleum Institute (USBM/API) method, involving the separation of acidic and basic compounds on ion-exchange resins, is described in Figure 4. The neutral eluting fraction is further fractionated by complexation with $FeCl_3$, yielding neutral nitrogen compounds and an oil fraction, consecutively separated on a silica–alumina column into saturates and aromatics.

The saturates–aromatics–resins–asphaltenes (SARA) method consists in a simplification of the USBM/API scheme. Instead of using separate columns, the consecutive ion-exchange resins and complexation materials are packaged in a single column. Two methods have been standardized (ASTM D2007 and D4124). Various separation, chemical treatment, and complexation procedures have been described.[3] The main drawback of all of these fractionations is that they are labor intensive and expensive, since they require large quantities of solvents and column packing. Furthermore, they were designed for preparative purpose in view of the subsequent characterization of the extracted fractions by analytical techniques. The recent evolution of analytical instrumentation towards ever more miniaturized systems eliminates the need for the production of large quantities of fractions since microgram quantities are now sufficient for most analytical determinations. As a consequence, chromatographic methods are moving from the preparative to the analytical scale.

Open-column liquid chromatography (LC) is advantageously replaced by medium- or high-pressure HPLC, which gives a much better resolution, requires smaller amounts of sample and is faster. Heavy and polar compounds are irreversibly adsorbed, causing column deterioration and incomplete elution, but this problem can be circumvented by an appropriate choice of stationary and mobile phases and column backflushing. The detection and quantitation of eluted fractions can be performed with a variety of detectors based upon refractive index, UV absorption, evaporative light scattering, etc. The coupling of HPLC with spectroscopic techniques can provide the direct analytical characterization of eluting fractions. Some hyphenated methods are described later.

5.3 Short-path Molecular Distillation

Although the definition of residues implies they have been produced after a preliminary distillation, short-path molecular distillation can yield additional distillate from

VRs.[4] In this low-pressure (10^{-2}–10^{-4} mmHg) distillation apparatus, the feed is introduced continuously and spread out by means of rotating paddles on a cylindrical warm wall. Partial vaporization occurs and, at a close distance, a coaxial condenser allows the vaporized fraction to be collected. The remaining residue is recovered in a separate collector. At the considered pressure, the distance between the cold and hot walls of the device is comparable to the mean molecular path of hydrocarbon molecules. Therefore, the separation process does not correspond to liquid–vapor equilibrium. The control of the hot-wall temperature up to 350 °C allows consecutive fractions to be prepared; it allows the production of 30–50% of distillate fraction from a VR. The mean molecular weight of the heavier distillate fraction may be as high as 800, corresponding to a 700 °C equivalent boiling point at atmospheric pressure.

5.4 Simulated Distillation by High-temperature Gas Chromatography

Simdist GC consists in the injection of a diluted sample into a precolumn (tubing diameter equivalent to column diameter). The column temperature is programmed and the vapors are continuously directed to a nonpolar gas–liquid capillary chromatographic column by an inert carrier gas flow and coupled with FID. The column performance in terms of resolution is not critical since the objective is not to perform a detailed separation but to obtain a global signal. Initially designed for distillate characterization, the range of application has been considerably extended since the introduction of stationary phases withstanding temperatures up to 440 °C, which allow the elution of hydrocarbons containing up to 120 carbon atoms (bp 720 °C). The column dimensions are usually 5 m × 0.5 mm i.d. Aluminum-coated silica columns withstand high temperatures but become breakable; metal columns are preferred. Since the FID response is directly proportional to the mass flow of carbon atoms eluted from the column, the resulting signal characterizes the differential flow of eluting material. The blank signal, resulting from the injection of pure solvent with the same temperature program, is subtracted from the analytical signal, thus producing a distribution of eluted mass % as a function of retention time. This scale can be converted to an equivalent atmospheric boiling point of *n*-alkanes through calibration with standard polyethylene waxes. Uneluted material is trapped in the precolumn section, which may be replaced. Quantitative determination of the eluting fraction requires the use of an internal standard in order to account for the uneluted portion of the sample. The deconvolution of simulated distillation curves can provide information related to the processing of residues.[5]

5.5 Supercritical Fluid Extraction

Supercritical fluids possess unique solvation properties and can be used as a mobile phase in chromatographic processes using either packed HPLC-type columns or capillary GC-type columns. According to the scale and objective of the separation (analytical or preparative), the process is referred to as supercritical fluid chromatography (SFC) or SFE. The most common and attractive fluid is CO_2, which is nontoxic and can be easily separated from the eluting material. Similarly to other chromatographic techniques, SFC can be coupled with standard detectors (FID, UV, etc.) and hyphenated with chromatographic or spectroscopic techniques. It has been applied to hydrocarbon group determination in residues and a comparative study with LC illustrated good quantitation for the evaluation of saturated, aromatic, and polar compounds.[6] Alternatively, simulated distillation can be achieved by SFC at moderate temperatures (150 °C) with capillary columns and gives a similar boiling-point distribution to high-temperature GC.[7]

6 CHARACTERIZATION OF FRACTIONS

6.1 Determination of Molecular Weight

A distinction must be made between colligative methods (based upon the modification of physical properties of solutions) and hydrodynamic methods. The former give access to the number-average molecular weight, W_n, and the latter, concerned with the apparent molecular size, allow the value of the weight-average molecular weight, W_w, to be determined.

In the former group of methods, cryometry and ebullioscopy have now largely been replaced by vapor pressure osmometry, which is easily automated. Instead of a direct determination of osmometric pressure, the flow of vapor from the pure solvent to the solution of sample is estimated through its thermal effect. The range of application is approximately 500–5000 (ASTM D2503).

The latter group of methods includes light scattering and viscosity. When a solution is illuminated by monochromatic light, the diffused intensity, extrapolated to zero concentration of solute, is a function of the radius of gyration of dissolved molecules, which in turn can be correlated with the mean molecular weight, introducing the variation of refractive index with concentration. The practical range of application is limited to molecular weights > 500.

The Mark–Houwink law establishes the relationship between intrinsic viscosity $[\eta]$ and molecular weight, W_w (Equation 4):

$$[\eta] = KW_w^{\alpha} \tag{4}$$

The coefficients K and α are related to molecular geometry, hydrodynamic behavior and solvent properties. Hence this is an indirect determination of molecular weight which can be applied over a wide range. A simplified standard method (ASTM D2502) has been proposed for petroleum-based fractions in a limited molecular-weight range (250–700). The ratio of weight-average to number-average molecular weight (W_w/W_n) is termed the polydispersity index and characterizes the heterogeneity of the sample. For instance, values as high as 4 can be observed for nonfractionated heavy crude samples, whilst that of asphaltene fractions is ca. 1.3. This indicates that the determination of a *mean* value of a given property of a complex, extremely dispersed sample is meaningless and that the information it provides is too vague to be useful.

As a consequence of the complexity of residues and fractions, the distribution of molecular weights is more meaningful than the mean value. It can be obtained by size-exclusion chromatography (SEC). In this technique, molecules are separated according to size variation in solution through permeation into the porous structure of a solid. The column packing generally consists of small particles (5–100 μm) of styrene–divinylbenzene copolymers possessing a pore structure in the range 10–100 nm. Elution is performed with solvents such as toluene, tetrahydrofuran, and chloroform. A large variety of detection methods can be applied, e.g. refractive index, UV absorption, fluorescence, and evaporative light scattering. Calibration of molecular-weight distribution is performed with polystyrene standards or normal paraffins for smaller values of W.

6.2 Determination of Aromatics and Saturates

The distribution and content of aromatic hydrocarbons in oil and oil/aromatic fractions is easily obtainable by UV absorption spectrophotometry, the experimental background of which is well established.[8] The exploitation of UV absorption spectra is based upon multicomponent analysis, which in turn relies upon the additive contribution of each component to the total absorbance at selected wavelengths. Typical attributions of wavelength ranges are as follows: monoaromatics, 195–200; diaromatics, 225–235; triaromatics, 250–258; chrysenes, 260–269; tetraphenes, 280–289; pyrenes, 332–350; and heavier polyaromatics, 385 nm.

Calibration consists in establishing a calculation matrix based upon known samples. Since no clear relationship exists between the molecular structure of a given compound and absorbance, many interferences may affect quantitative analysis. A correction for some identified interfering classes of compounds is possible in the calculation matrix. This is the case for heterocyclic compounds and pyrenes. However, other spectral interferences are more subtle and may be overlooked in commonly practised analytical methods. For instance, the interference caused by benzofluoranthenes is structure dependent: *g*, *h*, and *i* isomers interfere, whereas the *j* isomer does not. As a consequence of variable interferences, UV spectrophotometry may be considered as a fast, comparative method for the continuous monitoring of samples whose composition varies within restricted limits. Results are expressed as mole % aromatic content.

Low-resolution, high-ionization-voltage mass spectrometry (MS) has long been used for the quantitative determination of saturates and aromatics in oil fractions[9] (ASTM D2786). The method relies upon the resolution of a calculation matrix which accounts for the contribution of different classes of aliphatic and aromatic compounds to the production of selected ion fragments. A different approach consists in the use of a low ionization potential (field ionization) in order to maximize the yield of molecular ions. However, since numerous interferences occur, recourse to high resolution is necessary in order to discriminate compounds possessing an equivalent nominal molecular weight but different elemental compositions. The scope of the technique is limited to those products that are volatile at the maximum allowable source temperature (usually 350 °C), corresponding to a 550 °C atmospheric boiling temperature.

^{13}C- and ^{1}H-NMR spectroscopy (section 4.2) obviously can be applied to fractionated products for the determination of aromatic and aliphatic carbon and hydrogen.

6.3 Hyphenated Techniques

As mentioned earlier, an infinite variety of fractionation schemes and corresponding products can be designed. It therefore seems more efficient to proceed to a continuous determination of one specific property of fractions along with the separation process. This approach constitutes the basis for numerous combinations of analytical methods coupled with separation techniques.

Typically, a chromatographic method may be coupled with another chromatographic technique; numerous methods use the coupling of HPLC columns. The combination of normal-phase, reversed-phase, charge-transfer, and size-exclusion modes can be used to separate fractions of different polarity or size, and subsequently proceed to a further separation based upon another process. Similarly, the combination of HPLC and GC can be contemplated for volatile fractions. Chromatography can also be coupled with a specific detector, either an element-specific or multielement detector (e.g. atomic emission detector), or with a spectroscopic technique, e.g. TLC coupled with a UV detector or GC coupled with MS.

6.4 Determination of Individual Compounds

The presence of some target compounds in residue fractions deserves particular attention. This is the case with carcinogenic polycyclic aromatic hydrocarbons (PAHs), which can be concentrated on reversed-phase columns and further quantified by taking advantage of the selectivity of fluorescence detectors.

Metalloporphyrin complexes can be used as potential fingerprints of the origin of crude oils. They are selectively extracted from neutral heavy fractions with acetonitrile and may be further separated into nickel and vanadium groups by HPLC.

7 RATIONALIZATION OF ANALYTICAL DATA

The preceding fractionation and characterization techniques roughly distinguish paraffinic, naphthenic, and aromatic structures in residues. Since establishing an exhaustive inventory of individual molecular components in residues is a hopeless endeavor, structural group analysis (SGA) will attempt to describe the statistical distribution of structural elements, irrespective of the way in which they are combined in molecules, thus providing information intermediate between elemental and molecular analysis. Molecules in heavy fractions may simultaneously contain aromatic and naphthenic rings and paraffinic chains. Hence they cannot be classified according to the previously described separation schemes and they are better described in terms of structural fragment composition.

7.1 Determination of Structural Parameters from Physical Properties

In the early age of the petroleum industry, several simple methods, based upon the analysis of numerous samples, were developed for determining the distribution of carbon atoms (number of rings, percentage of carbon in rings) and hydrogen content from elemental analysis, refractive index, and density determination. For example, the $n–d–M$ method (ASTM D3298) is based upon the measurement of refractive index, density, and molecular weight at two temperatures. It allows the calculation of the percentage of aromatic carbon atoms, carbon atoms in ring structures, mean number of rings, and mean number of aromatic rings.

Numerous variations of these methods have been proposed, e.g. dispersion–refraction, density temperature coefficient, molecular weight–refractive index, and viscosity–density–refractive index. Owing to the empirical character of these methods and the need for some tedious measurements, spectroscopy-based SGA methods are currently preferred.

Table 3 ^{1}H- and ^{13}C-NMR band assignments

Structure type	Chemical shift (ppm from TMS)
Aromatic hydrogen	9.0–5.0
Hydrogen in CH, CH_2, CH_3, α to aromatic ring	5.0–1.9
Hydrogen in CH, CH_2, β or further to aromatic ring	1.9–1.0
Hydrogen in CH_3 γ or further to aromatic ring	1.0–0.5
Aromatic C	160–60
CH	60–37
CH_2 β or further to aromatic ring	37–24
CH_2 next to methyl or naphthenic	24–22.5
CH_3 α to aromatic ring	22.5–20
CH_3 β or further to aromatic ring	20.5–0

TMS, trimethylsilane.

7.2 Determination of Structural Parameters from Spectroscopic Methods

^{1}H-NMR and later ^{13}C-NMR have been extensively used to provide average molecule parameters as a description of petroleum derived fractions. The assignment of ^{1}H- and ^{13}C-NMR signals can be more refined than the simple distinction between aliphatic and aromatic entities presented in section 4.2. A summary of structure assignments is presented in Table 3. Thus, combining ^{1}H- and ^{13}C-NMR data, the following distribution of carbon atoms per mean molecule can be deduced: saturated carbon to aromatic ring; peripheral carbon in condensed ring systems; internal carbon in condensed ring; paraffinic methylene carbon further than α to aromatic ring; and paraffinic methyl carbon.

Additional parameters can be derived by combining NMR data and molecular-weight measurement, such as the degree of substitution of aromatic structures, the number of aromatic rings per molecule, and the number and length of alkyl substituents.[10]

This approach gives average parameters that may not provide information about the actual distribution of components in the mixture. The functional group analysis approach developed by Petrakis et al.[11] is based on the premise that although the molecules in heavy fractions may be extremely complex, they are composed of a limited number of functional groups. The chosen set must account for experimental data, and it must be as concise as possible. An illustrative list of functional groups is described in Table 4. Additional groups may be accounted for, provided that their contribution is relevant and in agreement with analytical data (e.g. oxygen or

Table 4 Definition of functional groups

Two ring hydroaromatic		Two ring hydroaromatic bridge	
nitrogen atoms). The concentration of the specified set of functional groups is introduced into a set of balance equations concerning the different structures (carbon and hydrogen atoms at different positions) derived from experimental data, with their respective stoichiometric coefficients. The resulting information has a definite superiority over average values of structural groups in the sense that it can be used for the quantitative description of complex samples and as a tool for elucidating reaction pathways. The contribution of estimated functional groups to thermodynamic properties, such as heat capacity,[12] can be evaluated.

This article discusses productivity enhancement which involves using an on-line digital process refractometer to determine the viscosity index (VI) of lube oil stocks. Since lube oils are Newtonian fluids, refractive index (RI) can be related to VI. A real-time continuous measurement of the RI has eliminated sampling, improved product consistency, reduced waste and has helped to optimize the process.

1 INTRODUCTION

In lube oil production the measurement and control of viscosity is vital. Goals such as uniform product quality and minimum waste can be achieved by continuous monitoring. Unlike periodical sampling, continuous monitoring provides instant feedback about changes in the process. This instant feedback is then used to control the process in real time.

2 VISCOSITY OF LUBRICATING OIL

Viscosity is the internal resistance to a shear force and is a complex property of a fluid. It is, however, a measurable property. The dynamic viscosity of a fluid will change with temperature and the way in which the shear is applied. Thicker fluids have a higher viscosity. Dynamic viscosity is defined by Equation (1):

$$\mu = \frac{\tau}{D} \tag{1}$$

where μ is the dynamic viscosity ($N\,s\,m^{-2}$ or poise), τ is the shear stress ($N\,m^{-2}$) and D is the shear rate (s^{-1}).

Fluids can be divided into two groups: Newtonian and non-Newtonian (see Figure 1). A Newtonian fluid is one in which the viscosity is independent of the shear rate. Examples of Newtonian fluids include water and oils. A non-Newtonian fluid is one in which the viscosity will differ depending upon the shear rate used in making the measurement. There are several types of non-Newtonian fluid. In order to obtain an accurate reading in a non-Newtonian fluid, the shear rate at which the measurement is made must be specified.

The kinematic viscosity of a fluid is the ratio of dynamic viscosity to density. Kinematic viscosity (ν) is expressed in either centistokes (cSt) or millimeters squared per second ($mm^2\,s^{-1}$) and is defined by Equation (2):

$$\nu = \frac{\mu}{\rho} \tag{2}$$

where ρ is the density ($kg\,m^{-3}$).

Lubricating oils with higher kinematic viscosity create a thicker film of the oil that will cling to a metal surface. Depending on the end-use of the lube oil, it may need to be very thin and free flowing or thick with a high resistance to flow. The rate of change of kinematic viscosity with temperature is the VI; it is a unitless number. A high VI indicates a smaller decrease in the kinematic viscosity with increasing temperature (see Table 1).

3 BASIC LUBE OIL PROCESSING

Crude oil is a mixture of various types of hydrocarbon. The crude oil type influences the VI of lube oil that can be produced. Naphthenic crude oils contain cyclic compounds and are used to produce low to medium VI base oils. High VI base oils are commonly made from paraffinic crude oils that contain mostly straight-chained hydrocarbons. The challenge to the refiner is the selection and blending of the crude type to optimize the production of the desired lube oil.

This crude oil mixture is first separated into useful fractions by thermal distillation. The products from thermal distillation are enhanced later by other unit processes such as catalytic cracking, hydrotreating, dewaxing and solvent extraction. Lube oil stocks contain wax and other contaminants that need removal before blending into products such as motor oils. This further processing helps to maximize the desired lube oil production.

Figure 1 Newtonian and non-Newtonian fluids; non-Newtonian pseudoplastic, ▬ Newtonian.

The propane extraction process removes undesired components. Propane is unique because it extracts both on the basis of molecular weight and by chemical structure. The propane is recovered with the resulting products being asphalt and deasphalted oil feed for the solvent extraction process.

Extractive solvent processing follows propane deasphalting. The most common extractive solvents used are furfural and phenol. The purpose of solvent extraction is to improve the VI, oxidation resistance and color of the lube base stock. After the solvent extraction process is complete, the resulting waxy stream is further processed either chemically or by catalytic methods.

There are several types of dewaxing solvent used in the refining industry. The most common solvent is MEK (methyl ethyl ketone). Most refiners charge the stream produced from the furfural or phenol refining unit to the dewaxing unit.

The types of result achieved in catalytic treatment depend on the type of catalyst used and the severity of the treatment. The pour point of a hydrocarbon liquid is the temperature at which it will no lower flow. Improving pour point is best achieved using a single catalyst. For color improvement and oxygen stability more than one catalyst may be required. Color improvement is directly related to the type of catalyst and operating conditions of the unit.

A summary of the various types of lube oil processes is given in Table 2.

The use of a reliable in-line measurement technique can eliminate sampling and time-consuming laboratory testing for the determination of the VI of oil. The laboratory method for the determination of the VI of lube oil is the American Society for Testing and Materials (ASTM) D 2270-93, the VI is the rate of change of the measured kinematic viscosity. For the calculation of a VI when the kinematic viscosity at 100 °C is less than 70 cSt Equation (3) is used:

$$\mathrm{VI} = \frac{L - U}{L - H} \times 100 \tag{3}$$

where U is the kinematic viscosity at 40 °C ($mm^2\,s^{-1}$ or cSt), L is the kinematic viscosity at 40 °C of an oil of 0 VI (from Table 1 of ASTM D 2270-93) and H is the kinematic viscosity at 40 °C of an oil of 100 VI (from Table 1 of ASTM D 2270-93). For ν values greater than 70 cSt the ASTM method uses another equation.

The relationship between RI and VI for a given crude or crude blend is established by laboratory testing and then confirmed by sampling at a prescribed interval. Based on the results of the laboratory tests, ASTM D 1747-89, the refinery can set target RI values for the process. The final quality or final VI of the lube oil can then be controlled and measured by the in-line refractometer.

Table 2 Processes for finishing lube oils

Process	Function
Solvent (propane) deasphalting	Reduces carbon and sludge formation
Solvent extraction	Improves VI
Solvent dewaxing	Lowers pour point
Catalytic hydrotreating	Improves color and oxygen stability
	Lowers organic acidity

4 REFRACTIVE INDEX THEORY

RI is a measure of the amount of bending or refraction that occurs when light passes from one medium to another. This is caused by the change in the speed of light in each medium. In addition to varying with the medium, the response changes with the concentration of the dissolved solids. The mathematical equation for this principle is known as ''Snell's law'' defined as, Equation (4):

$$\sin i = n \sin r \tag{4}$$

Table 1 Typical values of VI for lubricating oils

Oil type	SAE	°API	Viscosity (cSt) at 40 °C	VI
Gear lubricants	90	28	150–200	95–98
Motor oils	10W–40	30	70–75	120–140
Synthetic oils	5W–40	33	80–90	150–160

SAE, Society of Automotive Engineers; °API, American Petroleum Institute gravity.

where i is the angle of incidence, r is the angle of refraction and n is the RI.

The critical angle (Figure 2) is the point or angle at which light refraction ends and total reflection starts. This is defined by Equation (5):

$$\sin c = \frac{n_1}{n_2} \tag{5}$$

where c is the critical angle, n_1 is the RI of first medium and n_2 is the RI of second medium.

However, it was not until 1874, with the invention of the refractometer by Ernst Abbe, that RI became practical to measure.

5 IN-LINE REFRACTOMETER

The primary measurement of a process refractometer is RI. This is done by directing light through a prism at various angles to the interface between the prism and the liquid being measured. This creates both refracted and reflected light rays that form a light and dark image. The critical angle occurs at the transition or borderline that differentiates the refracted and reflected portion of this optical image. This borderline position changes with RI and/or the dissolved solids concentration.

Figure 2 Critical angle.

Figure 3 Digital analysis of optical image by CCD.

The in-line process refractometer uses a charge-coupled device (CCD) microchip to determine the position of the borderline and relate its position to RI. The use of the CCD microchip replaces the human eye that serves this function in the case of a hand-held and/or a laboratory refractometer. The CCD then converts this optical image into a digital signal (Figure 3). This conversion eliminates drift and increases the stability of the measurement. The second component to any RI measurement is temperature: RI is temperature dependent and, hence, a correct temperature measurement is important. Only by the correct combination of these two measurements can a stable, accurate and reliable RI value be generated.

The relationship between °API or API gravity of an oil (a density term used in the petroleum industry) and RI is proportional. °API can be defined by Equation (6):

$$^{\circ}\text{API} = \frac{141.5}{\text{specific gravity of the oil}} - 131.5 \tag{6}$$

Specific gravity equals the density of liquid divided by the density of water. Water has a specific gravity of 1.0 and an API gravity of 10°. Materials with high API gravity are lighter and lower in density. The reverse is true for specific gravity.

However, RI can be directly measured whereas °API is calculated. This is why RI has been found to be a more reliable process parameter to monitor. The range of RI at 70 °C for a lube oil varies from 1.4400 to about 1.5000. An accurate in-line determination of RI is required because a change in the RI between 0.0007 to 0.0010 RI units, can result in a change of 1 unit in the final VI of nonprocessed lube oil. The exact magnitude of the change will depend on the oil type and the initial °API of the oil being processed. In general, the change in VI for heavy, high °API, naphthenic-type feeds tends to be greater then that of lighter, lower °API, more paraffinic feeds (Figure 4).

Mounting and location of the prism are important to the measurement. As well as improving the temperature indication, being angled and having an intrusive design promotes self-cleaning. The angle creates turbulent flow and locating away from pipe walls keeps the prism at the same temperature as the process fluid. A minimum velocity is maintained so that self-cleaning can occur and a fresh sample is constantly provided for the measurement. In some lube oil applications the self-cleaning is sometimes supplemented by a steam washing system. The in-line refractometer should be installed in a sample line so that temperature variations are minimized; temperature control is usually done by a heat exchanger. This location assures that any sample collected and later tested by the laboratory will be identical to that measured by the in-line refractometer (Figure 5).

Figure 4 Sensitivity of lube oil VI response.

Figure 5 In-line refractometer.

The instrumentation hardware costs for an in-line refractometer are typically below that of other in-line measurement techniques. The final hardware cost is influenced by such factors as cable run, prism washing options and the area classification requirements. This makes refractometers very attractive and competitive as an analytical option.

6 CASE STUDIES

A large lube oil producer has installed several digital process refractometers in their refineries. These units have been in operation for several years. According to one process engineer associated with the project the digital process refractometers operated as expected and provided accurate and repeatable RI numbers. This on-line RI information is then used to predict the final lube oil VI and to adjust the efficiency of the process.

Several types of process change can affect VI, such as, blend stock source and extraction tower temperature. There is a finite residence time for the effect of a given process change to pass through the process unit. However, laboratory samples can be delayed and their results determined well after the unit has been affected. The installation of an in-line device is required to establish an exact correlation between process changes and VI (Figure 6). This delay time can increase production costs and reduce product quality.

A major gulf coast lube oil facility produces a variety of motor oil and lubrication products. Their process is based on Chevron's ISODEWAXING® technology and is designed to operate on a wide variety of crude oils.

Owing to variability of the feed, a reliable and accurate method is required to characterize the process. This refinery makes frequent changes in the crude feed. Changes in the crude feed increase the risk of making off-target product which may contaminate a finished product tank.

Contamination of a finished product tank can adversely affect the refinery in several ways. First, it reduces overall refinery capacity owing to a lack of storage for new production. Second, it tends to reduce net unit feed because the off-test material must be blended in with fresh feed. This is especially costly if the affected unit is currently at its maximum capacity.

This location has two digital process refractometers installed in its new catalytic hydrotreater dewaxing lube oil unit that processes about 10 000 barrels per day or

Figure 6 Response of in-line refractometer.

Table 3 Paraffinic base oil prices (April 1998)

Viscosity grade	Price range (cents/gallon)
Light (90–150)	87–110
Medium (200–250)	87–110
Heavy (500–600)	100–111
Bright Stock	123–134

Source: *Hart's Lubricants World.*

420 000 US gallons per day. These refractometers were commissioned early in 1997; the start-up was very simple. According to the process engineer, both units have been stable and very reliable. This plant has found the RI measurement useful during crude blend shifting. The RI reading is used to identify and predict when possibly off-test VI material is going into final product tanks and when best to collect lab samples. If the RI reading is outside the normal level it has been found that the VI will also be outside the required specifications. In this case, the off-test product is diverted from the finished product tank. Operations estimated that because they have avoided producing off-test material, the pay back time for the refractometer was very short, based on the price of lube oil (see Table 3).

7 CONCLUSION

Both viscosity and RI are physical properties of a fluid. They have both been measured by one or more methods for several years. Although laboratory test procedures and protocols are well established in a modern refinery, they can never respond with the speed of an in-line instrument. The profitability of the lube oil unit is related to its ability to obtain quick, accurate and reliable VI information in order to make the correct adjustments to the process.

The following can be stated about the relationship between RI and lube oil VI:

- RI measurement of lube oils has traditionally been done in the laboratory, but now it has moved into the process environment. The process measurement of RI is now reliable, simple and cost effective.
- An in-line process measurement of RI can be used as a real-time predictive tool for the final VI of lube oils in the quickly changing production environment. A quick and accurate response is needed in order to optimize production.
- RI can identify and predict when possibly off-test VI material is going into finished product tanks. Contamination of a finished product tank can adversely affect both the economics and operations of a refinery.

The chemical complexity of petroleum products has, until recently, precluded calculational techniques based on a definitive analysis of the molecular species involved. Instead, readily observed or easily (quick and inexpensively) measured macroscopic properties (gravity, boiling range, etc.) have been used to correlate information empirically. In some instances, the predictions have been "tweaked" on a local data-centric basis or extended by quasi-theoretical analysis.

Recent computer-aided advancements[134] in multivariate electromagnetic emission, NMR (nuclear magnetic resonance) and/or MS (mass spectroscopy) analyses allow for the reliable and repeatable use of much more detailed experimental data. The ability to speciate cuts by individual chemical components will revolutionize both refining and regulation of refined products in response to the availability of quality data.

So why would one bother with older analysis and prediction methods? It is likely, given the operational sophistication and investment costs needed to deliver this highly speciated information properly, that the old ways will die but slowly. Most refineries and petrochemical plants try to get by with the minimum amount of expensive on-line analyzers. Multivariate data generation is not yet at a state where it can easily be used for real-time process or even product quality control. This barrier will exist for some time to come.

The historical development of crude oil processing technology has generated a great volume of data and "general" correlations, some contradictory. Most of the data upon which these methods are based have been around for 60 or more years. Many have withstood the "test of time", being examined and verified by numerous researchers both public and private. Some of the precision of the older data may not be as good as what is generated today, but new entries to various refinery products' databanks seem to confirm the validity of the best of the older procedures and data.

The classical methods allow one to impute several otherwise unavailable characterizing pieces of data. It is essential that those engaged in the design and analysis of refinery units (which have multiple feed and product streams) become familiar with classical terminology and techniques, and eventually acquire an intuitive sense of what constitutes the "best answer" when confronted with several conflicting alternatives. The subject of this article is the proper methodology of imputing this knowledge from whatever data are at hand.

1 HYDROCARBON CHARACTERIZATION AND PROPERTY PREDICTION VIA INSPECTION PROPERTIES

1.1 Introduction

The chemical complexity of petroleum products has, until recently, precluded calculational techniques based on a definitive analysis of the molecular species involved. Instead, readily observed or easily (quick and inexpensively) measured microscopic properties (gravity, boiling range, etc.) have been used to correlate empirical information. In some instances, the data have been ''tweaked'' on a local ''crude-feed'' basis or have been extended by quasi-theoretical analysis. A list of the more common inspection properties for petroleum-derived fuels products is given in Table 1.

Recent computer-aided advancements[134] in multivariate electromagnetic emission, NMR and/or MS spectral analyses allow for the use of such experimental data in real time. The ability to speciate cuts by individual chemical components will revolutionize both refining and regulation of refined products in response to the availability of quality data.

So why would one bother with older analysis and prediction methods? It is likely, given the sophistication and investment costs required to deliver this highly speciated information properly, that the old ways will not die out for a long time; some of them never. Most refineries and petrochemical plants try to get by with the minimum amount of expensive on-line analyzers. Multivariate data generation is not yet at a state where it can easily be used for real-time process or business control. It is likely that this barrier will exist for some time to come.

The classical methods allow one to impute several otherwise unavailable characterizing pieces of data. It is essential that those engaged in the design and analysis of refinery units (which have multiple feed and product streams) become familiar with classical terminology and techniques, and eventually acquire an intuitive sense of what constitutes the ''best answer'' when confronted with several conflicting alternatives. The subject of this article is the proper methodology of imputing this knowledge from whatever data is at hand.

The historical development of crude oil processing technology has generated a great volume of data and ''general'' correlations, many contradictory, and which can be a source of frustration to those accustomed to relatively rigorous true component calculations. Most of the data upon which these methods are based have been around for 60 or more years. They have withstood the ''test of time'', being examined and verified by numerous researchers both public and private. Some of the precision of the older data may not be as good as what is generated today, but new entries to various refinery products' databanks seem to confirm the general efficacy of the older methods and data.

Then, too, a mere listing of components and relative amounts does not always mean that the important processing properties of the stream can be estimated

Table 1 Typical refining inspection properties

- AP
- API gravity
- Bromine(or iodine) number
- CN: Diesel fuel ignition characteristics
- CP
- Distillation data (different types of):
- ASTM D-86 distillation (760 mmHg)
- ASTM D-1160 distillation (usually at 10 mmHg)
- TBP distillation (15/5 distillation at 760 mmHg)
- ASTM D-2887/D-3710(GC Method at 760 mmHg)
- FP
- FRP
- Heat of combustion
- Octane numbers: antiknock characteristics
- PONA analysis (observed/calculated measurement)
- PP
- RC/CC/BMCI
- RI
- RVP
- SP
- Viscosity

The following properties are so quickly and easily derived from basic measured inspection data that they are typically included as a part of the inter-property relationships:

- Watson K factor and other compositional indices
- MW (derived/measured)
- CI
- DI
- Temperature at which $V/L = 20$
- Thermal capacity and transport properties:
  1. Heat of combustion
  2. Heat of vaporization
  3. Thermal heat capacity
  4. Thermal conductivity

The following properties are often measured in a normal sampling in most refineries. They have little bearing on general predictive techniques and will not be mentioned beyond this summary.

- Penetration index for asphalt (observed measurement)
- BS & W content (wt%)(observed measurement)
- Copper number (observed measurement)
- Doctor test (observed measurement)

AP, aniline point; API, American Petroleum Institute; CN, cetane number; CP, cloud point; ASTM, American Society for Testing and Materials; TBP, true boiling point; GC, gas chromatography; FP, flash point; FRP, freeze point; PONA, paraffins, olefins, naphthenes and aromatics; PP, pour point; RC, Ramsbottom carbon number; CC, Conradson carbon number; BMCI, Bureau of Mines correlation index; RI, refractive index; RVP, Reid vapor pressure; SP, smoke point; MW, molecular weight; CI, cetane index; DI, diesel index; BS & W, bottom sediment and water.

accurately. In cases of MWs and critical properties, the multispectral analyses predict well. In the areas of transport properties, such as viscosity and thermal conductivity, predictions from mixtures of pure components, by most published research work, have been patchy at best. Although some efforts have been made public in quantifying the contributory effects of molecular structural interactions, little has been published that is of general value. There will certainly be more opportunities for research in this area, but the current technology will be used to augment and extend pure lab data for the next 10–20 years.

In any event, these correlations have been useful to the author and can be utilized, for lack of any other need, as a check on the values derived from more directly analytical methods.

For editorial purposes, several liberties have been taken in construction of this article. For one, several acronyms are employed in place of explicitly named properties. For example, AP is aniline point, SG is specific gravity, etc. We make so many references to such properties here, both in the text and in equations, that to spell them out time and again would drastically increase the length of the article. We also have relied heavily on two primary compendia of timely information. These are the ASTM standards,[19–49] and the API Technical Data Book.[9–16] Mention of any of these sources in the articles should be considered as an implicit reference. To repeatedly denote them separately would increase text length dramatically. Then too, each of these magnificent documentation sources are constantly being revised and improved. The reader is strongly advised to refer to the *latest* versions of each relevant document, which are readily available from the two organizations, as well as from other many other purveyors of technical information. Finally, several of the correlations and calculation methods are reported here in units other than standard SI, the default for this encyclopedia. In some cases where clarity and brevity allow, we have provided both sets of units. In other cases, we have reported the units as described in the original information source, to avoid transcription errors or in cases where prevailing standards and specifications (or simply potential user bias and familiarity) call for the values in, perhaps, Imperial standard units as opposed to metric. The reader is advised to bear this in mind, especially when dealing with correlations requiring absolute temperatures, such as with the Kelvin or Rankine scales.

1.2 Summary Description of Petroleum Inspection Properties

Among many different types of petroleum properties, the following are the ones that should be considered in order to understand petroleum processing technologies.

The first set of inspection properties are typically measured as a normal daily or even hourly quality control effort. In a few cases, on-line analyzers can be used for real-time process control. The requirement for this capability is the ability to obtain, analyze and report accurately the findings to the process feedback control system on a timely basis (30 s to 20 min, typically).

1.2.1 Aniline Point

The AP is the minimum temperature for complete miscibility of equal volumes of aniline and the sample under test. It is a measure of paraffinicity of petroleum fractions; the higher the AP, the higher is the paraffin content. The standard test for this method is ASTM procedure D-611.

1.2.2 American Petroleum Institute Gravity

The API density standard is by definition (Equation 1):

$$\text{SG} = \frac{141.5}{131.5 + \text{API gravity}} \tag{1}$$

Therefore, by mathematical manipulation (Equation 2):

$$\text{API gravity} = \frac{141.5}{\text{SG}} - 131.5 \tag{2}$$

The standard test for this SG of a petroleum cut is ASTM procedure D-4502.

1.2.3 Bromine (or Iodine) Number

The bromine number is the number of grams of bromine consumed under specified test conditions by 100 g of sample. Bromine number is a measure of olefinicity of a petroleum fraction; the higher the bromine number, the higher is the olefinic content. Iodine is sometimes used for this test instead.

1.2.4 Cetane Index/Cetane Number: Diesel Ignition Characteristics

The cetane number (CN) is the diesel fuel analog to gasoline octane. It is defined (ASTM D-613) as the percentage of normal cetane that must be added to heptamethylnonane in order to match the ignition characteristics of the fuel undergoing tests. Typical refinery diesel stock CNs vary from 35.0 to 50.0.

The CI is a useful calculation for estimating the CN without experiment.

1.2.5 Cloud Point

This is the temperature at which paraffinic waxes (or other high MW components) just start to crystallize

and cause the stock to appear cloudy or hazy. This is a constraint temperature for fuels that must perform in low temperatures (−20 °F and below). Jet fuels and arctic winter gasolines are two such products. The CP is also an important characteristic of lubricants that need to perform in cold temperatures. The formation of wax crystals that can form will inhibit the lubrication effectiveness.

The standard test for this method is ASTM procedure D-2500.

1.2.6 Distillation Data (Different Types of)

1.2.6.1 American Society for Testing and Materials D-86 Distillation (760 mmHg)

- Gasoline
- Distillate

1.2.6.2 American Society for Testing and Materials D-1160 Distillation (Usually at 10 mmHg)

- Heavy oils
- Residuum
- Fractionator bottoms

1.2.6.3 True Boiling Point Distillation (15/5 Distillation at 760 mmHg)

- 15 stages and 5 reflux ratio
- Approximate true boiling temperatures
- Used for blending of fractions
- Pseudo-component generation from the distillation
- This test has several variations in common use but ASTM D-2892 is as close to a standard as exists.

1.2.6.4 American Society for Testing and Materials D-2887/D-3710 (Gas Chromatography Methods at 760 mmHg)

- Programmed GC calibrated to type (boiling range) of stocks (gasoline, kerosine, diesel, etc.). They can be readily correlated to D-86 and TBP and are quick and repeatable up to heavy ends [1000 °F normal boiling point (NBP) maximum] distillation range.

1.2.7 Flash Point

This the lowest temperature to which the substance must be heated in air to form a mixture containing sufficient vapor to be ignited momentarily by a flame under a specific condition. The test methods used are the Cleveland open cup (ASTM D-92), Pensky Martins closed cup (ASTM D-93) and TAG closed cup standard (ASTM D-56). The FP is important in the handling of volatile products such as cleaning solvents and gasolines. For heavier stocks, the FP is used to estimate the oil's ability to vaporize under certain conditions, which affects both the oil's potential flammability hazard and the consumption rate of the oil.

1.2.8 Freeze Point

This parameter is similar to CP but according to a slightly different procedure. It is defined by ASTM D-2386 as the temperature at which the first solid hydrocarbon crystals, which are formed as the sample of the hydrocarbon is slowly cooled with agitation, disappear upon slight heating. Again, cold weather performance of the fuel is the critical property of concern here.

1.2.9 Octane Number: Anti-knock Characteristics

This is defined as the volume percentage of isooctane that must be mixed with *n*-heptane in order to match the knock intensity of the diesel fuel undergoing testing.

Octane number of isooctane = 100.
Octane number of *n*-heptane = 0.0.
Research octane number: engine speed 900 rpm.
Motor octane number: engine speed 600 rpm.

1.2.10 Paraffins, Olefins, Naphthenes and Aromatics Analysis (Observed/Calculated Measurement)

The PONA in a petroleum fraction is often obtained by a combination of GC, NMR and infrared (IR) methods and inspection properties or by multivariate analysis of one or more of these. There are several ASTM standards for a multitude of tests that can be used to gather this information.

1.2.11 Pour Point (American Society for Testing and Materials D-97)

The PP is the lowest temperature at which a high MW hydrocarbon mass starts to pour. A solidified quantity is slowly heated (in 3 °C steps) and tilted to see if the solid mass starts to flow within 5 s. The temperature at which perceptible flow occurs is recorded as the PP. This property is useful in determining some of the processing properties of heavier cuts. Cold weather flow performance of the fuel or lubricant stock is the major concern addressed by this standard.

1.2.12 Ramsbottom Carbon/Conradson Carbon/Bureau of Mines Correlation Index

These tests determine the percentage (wt%) of residue left after pyrolytic carbonization of a petroleum fraction. This is usually done for residuum or fractionator bottoms product. They are a measure of how much coke it will

make in coking processes. All lubricating oils leave behind ''carbonaceous'' deposits at high temperature as well. Deposits of these materials can ultimately affect the engine's performance.

The ASTM D-189 method is used for Conradson carbon and the ASTM D-524 method for Ramsbottom carbon contents. The BMCI is another method of defining the carbon residue of shale oils.[57]

1.2.13 Refractive Index

The RI represents the ability of a liquid to bend and distort the travel path of light across the air–liquid boundary. It is a fairly simple and repeatable test. RI is a basic parameter for determination of aromatics content and, when combined with viscosity, provides a quality estimate of MW. ASTM D-1218 is the controlling standard.

1.2.14 Reid Vapor Pressure

RVP is an approximation of the vapor pressure of naphtha and distillate range petroleum fractions at 100 °F, the estimated automobile carburetor or injector inlet temperature. RVP also gives the refiner an indication of how much light hydrocarbons (especially *n*-butane) are contained in a petroleum fraction. Three ASTM standards, D-323, D-4956 and D-5191, are used to ensure the quality of the data.

1.2.15 Smoke Point (American Society for Testing and Materials D-1322)

The SP is a measure of burning cleanliness of jet fuel or kerosine. It is defined by the ASTM standard as the maximum flame height (millimeters) at which a fuel will burn without smoking. The SP is low for a fuel having a high smoking tendency. In general, removal of aromatic content increases the SP. An SP > 17 is generally acceptable.

1.2.16 Viscosity

Viscosity is an important control property for lube oils and often for some heavy cracked products. There are at least eight scales by which these data can be reported. For most correlations, either centipoise or centistokes is required. This may necessitate some calculations in addition to the primary measurement data one takes in the laboratory. This article will not concern itself with such conversions as they are widely presented elsewhere in the literature.

The following properties are so quickly and easily derived from basic measured inspection data that they are typically included as a part of the inter-property relationships.

1.2.17 Watson K Factor

The most important derived property (sometimes called the UOP *K* factor) is the Watson *K* (K_W) or characterization factor. It is defined by Equation (3):

$$K_W = \frac{[\text{weight-average boiling point } (^\circ\text{R})]^{1/3}}{\text{SG}} \quad (3)$$

It is a measure of the distribution of different types of molecules (paraffins, naphthenes and aromatics) in a petroleum fraction. The higher the K_W factor, the higher is the paraffinicity, and the lower the K_W factor, the higher is the aromatics content. For most refinery stocks K_W varies from 10.0 to 13.0 in general. Note the use of absolute temperature scales in calculating K_W.

Three other compositional characterization factors are used to a limited extent with petroleum fractions. These are the viscosity–gravity constant, the Huang factor and the refracticity index. They will be discussed in limited detail. Most of the methods and data work done to date in this field have involved the K_W factor far more than any other.

1.2.18 Molecular Weight (Derived/Measured)

The molecular weight (MW) can actually be estimated by laboratory procedures,[78,111] but these are slow and labor intensive, so they are very rarely performed in an operations setting.

1.2.19 Cetane Index: Diesel Fuel Ignition Characteristics

The CI is a derived property that is roughly approximated to measured CNs. Direct analysis of CN is a difficult measurement and several correlations have been developed to permit operations to estimate the CI based on other observed properties.

1.2.20 Diesel Index

This is given by Equation (4):

$$\text{DI} = \frac{(\text{AP})\ (\text{API gravity})}{100} \quad (4)$$

This is also an indication of paraffinicity of a petroleum fraction.

1.2.21 Temperature at which V/L = *20*

T at $V/L = 20$ is a fuel specification requirement for most gasolines. It is obtained from the TBP curve with estimates of vapor and liquid volumes where the ratio of the two is 20 : 1. As such, it is easier to derive than to measure.

1.2.22 Thermal Capacity and Transport Properties

This category of properties is most important in the design and prediction of refinery operations. Many of these can be measured directly in the laboratory but few with any simplicity. Derivation of values is then the preferred and a usually accurate alternative in this case.

The properties considered here are outlined below.

1.2.22.1 Heat of Combustion An important property of all fuels is the heat of combustion, since this is a measure of the energy available from the fuel. A knowledge of this value is essential when considering the thermal efficiency of equipment for producing either power or heat. ASTM D-240 is used for the direct determination of heats of combustion of aviation gasolines and of fuel oils. Net heats of combustion of petroleum fuels vary from $45\,925\,kJ\,kg^{-1}$ ($19\,774\,Btu\,lb^{-1}$) for propane to $33\,029\,kJ\,kg^{-1}$ ($14\,200\,Btu\,lb^{-1}$) for petroleum coke. Ordinary calorimetric techniques are employed.

1.2.22.2 Heat of Vaporization Proper and safe separation of hydrocarbons by vapor–liquid equilibria requires an accurate knowledge of the heats of vaporization. This is an important variable for calculating heating duties and thermal processing equipment sizes.

1.2.22.3 Heat Capacity of Liquid–Vapor Prediction of liquid and vapor behavior under heat transfer conditions is of great concern. This is an important variable for calculating details of thermal processing and distillation equipment.

1.2.22.4 Thermal Conductivity of Liquid–Vapor Prediction of this property is often an inaccurate procedure. With hydrocarbons, however, it is surprisingly good. This is also an important variable for calculating details of design and operation of thermal processing equipment.

1.2.22.5 Critical Properties For a pure component, the critical state can be summarized by three interrelated thermodynamic parameters – the critical temperature, critical pressure and critical density. The critical temperature is defined as that temperature above which a gas cannot be liquefied by an increase in pressure. The maximum pressure that will result in formation of a separate liquid phase at the critical temperature is called the critical pressure. The density of a fluid at its critical temperature and pressure is its critical density.

When dealing with mixtures of two or more compounds, this precise definition needs some refining. In theory, there is a state in which all intensive properties of the coexisting liquid and vapor phases become continuously identical. Corresponding states correlations that depend upon a reasonable estimate of the critical state work best with what are known as ''pseudocritical'' quantities. These are traditionally defined as the molar average of the critical temperature and pressure.

The following properties are typical items also measured in a normal sampling in most refineries. With the exception of the asphalt test, they all measure contamination levels. They have little bearing on general predictive techniques and will not be mentioned beyond this summary.

1.2.23 Penetration Index for Asphalt (Observed Measurement)

This is the depth (in millimeters) that a standard needle penetrates vertically into a sample of the asphalt material under specific test conditions.

1.2.24 Bottom Sediment and Water Content (Observed Measurement)

This is a measure of basic sediment and water absorbed and contaminating full-range crude and other hydrocarbon fractions.

1.2.25 Copper Number (Observed Measurement)

This is the amount (milligrams) of mercaptan sulfur in 100 mL of oil sample. It is used to measure mercaptan content in a general petroleum fraction.

1.2.26 Doctor Test (Observed Measurement)

Sodium plumbite solution is used to measure mercaptan content in a gasoline stock.

1.3 Chemical Compositions of Petroleum Fractions

To grasp fully the relationship between performance and fuel properties, is essential to understand the chemical composition of the fuel. This is currently done at great difficulty and expense, but enough data exist that several generalizations can be formulated.

1.3.1 Broad Component Classification of Hydrocarbons[41,56,59,68]

Petroleum and coal-based liquid hydrocarbons contain chemical species from a list of over 1600 pure hydrocarbons and several related compounds. Nearly every crude oil has 300–800 measurable species at some detectable level. Among the categories are the following:

1. Paraffins (alkanes)
   - Straight chain (normal)
   - Branched chain (iso)

Table 2 Typical crude assay ranges[3,7,72,73][a]

Source	Boiling point range of crude (°F)	Volume-% distilled at end boiling point	SG range of crude	MW range of crude
Kuwait crude oil	104–2102	100.0	0.6285–1.10	77–1668
Venezuelan crude oil	195–533	36.0	0.746–0.9593	195–353
Saudi Arabian crude oil	78–963	80.0	0.645–0.9254	68–484
Abu Dhabi crude oil	104–932	87.04	0.6285–0.9465	77–450
Sumatran crude oil	99–934	73.7	0.685–0.892	70–477
Iranian crude oil	93–1022	78.4	0.654–0.9285	71–532
Iraq crude oil	104–2012	100.0	0.628–1.10	77–1532
Qatar crude oil	104–1652	100.0	0.6285–1.054	77–1097

[a] The TBP ranges of the crude are not always complete. Very often, the assay is reported only to the last tangible cut range above the tower resid. This may be diesel, or more likely gas-oil material. Measuring the resid properties often seemed superfluous and unnecessary. Obtaining accurate temperatures and recovery percentages is also very difficult for temperatures much above 800 °F and certainly for those above 1000 °F. Many petroleums have estimated end-points between 1300 and 2000 °F.

Table 3 Typical hydrocarbon assay molecular analysis[94,99,101,102]

Petroleum fraction	MW	Critical temperature (°F)	Critical pressure (psia)	Molecular type analysis (vol%)				
				Paraffin	Naphthene	Olefin	Aromatic	S compounds
1. California naphtha	102.4	536.7	532	36.2	58.2	0.0	5.6	0.0
2. Alaska naphtha	131	626.5	414.7	39.7	39.6	0.0	20.5	0.0
3. Aromatic naphtha	126	626	709	0.0	0.0	16.9	83.1	0.0
4. Jet fuel	144	665	440	18.6	69.8	0.0	10.6	1.0
5. Light naphtha	120	605	463	61.9	30.6	0.0	7.6	0.0
6. Heavy naphtha	142.4	646	371	59.3	30.8	0.0	9.9	0.0
7. Kerosine	162.3	739	361	30.9	64.3	0.0	4.8	0.0
8. Fuel oil	227.5	879	290	29.8	45.6	0.0	22.4	1.3
9. Gas oil	214	868	280	38.8	41.5	0.0	17.2	2.4

2. Cycloparaffins (naphthenes)
   - Single ring
   - Multi-ring
3. Olefins
   - Aliphatic olefins
   - Cycloolefins
4. Aromatics (with/without attached chains)
   - Single ring
   - Multi-ring
5. Sulfur compounds
   - Mercaptans (thiols)
   - Thiophenes (simple, multi-ring)
6. Nitrogen Compounds
   - Amines
   - Pyridine

In general, petroleum fractions are made of combinations of the above components in MW structures ranging from 2 to >600. Tables 2–4 present type and characterization breakdowns of various crude oils and their typical refinery cut fractions.

1.3.2 Crude Oil Analysis by Fractional Product Content[1–18,51,57,72]

Crude oil distillation separates the basic components of petroleum into various streams, mostly on the basis of boiling point. Gasolines, kerosines, diesel, gas-oils, resids, etc. are all standard refinery terminology for some of these cuts. Refer to the glossary if a more detailed explanation is necessary.

A typical crude oil can be described compositionally in several ways:

- A typical crude oil composition speciated by pure boiling range cut fractions is presented in Figure 1.
- Relative amounts of hydrocarbon types in a crude oil are displayed in Figure 2.
- A textual listing of a typical crude fraction assay is presented in Table 4.
- A graphical display of the boiling point curve typical of crude assays is shown in Figure 3.
- The delineation of various products based on TBP value is demonstrated in Figure 4.

Table 4 Typical crude oil assay[3,99,101,102,150,151]

Name, state, and country	Boscan, Zulia, Venezuela	Kern River, CA, USA	Quitman, MS, USA	Tia Juana, Zulia, Venezuela	Gato Ridire, CA, USA	Bachaquero, Zulia, Venezuela
Gravity (API)	9.5	10.7	12.7	13.3	13.8	14.0
Sulfur (wt%)	5.25	1.23	3.85	2.66	5.21	2.64
Viscosity (SSU at 100 °F)	–	6000+	–	452 at 210 °F	6000+	–
Characterization factor:						
at 250 °F	12.20	–	11.9	–	11.62	11.75
at 450 °F	11.60	11.13	12.1	11.40	11.28	11.40
at 550 °F	11.40	11.15	11.85	11.40	11.20	11.15
at 750 °F	11.40	11.15	11.55	11.30	11.20	11.30
Gasoline:						
Octane No. clear	–	–	–	–	–	72.4
% to 400 °F	3.8	1.2	9.4	1.4	11.3	5.0
Octane No. clear	42.0	–	42.5	62.0	67.0	68.0
% to 450 °F	5.2	2.2	11.4	2.9	14.2	7.5
Kerosine distillate:						
% 375–500 °F	4.1	2.7	5.9	4.2	7.5	7.0
API gravity	39.2	32.5	45.0	36.2	33.9	35.0
SP (mm)	19.2	13.0	29.0	15.7	14.5	16.0
Sulfur (wt%)	3.0	0.38	0.75	0.56	2.25	0.50
Distillate or diesel fuel:						
% to 400–700 °F	16.0	19.7	21.0	21.3	20.0	22.5
DI	26.0	30.0	48.0	39.0	32.0	33.0
PP (°F)	−35.0	−30.0	3.0	−40.0	−30.0	−35.0
Sulfur (wt%)	3.3	0.8	1.7	1.3	3.1	1.1
Lube distillate:						
% to 700–900 °F	12.8	22.2	17.6	23.2	14.8	19.0
PP (°F)	55.0	–	–	−5.0	–	−10.0
Viscosity index	25.0	–	37.0	−20.0	−19.0	−17.0
Sulfur (wt%)	4.3	1.5	2.65	2.30	4.5	2.25
Residue (% over 900 °F)	67.4	57.0	52.0	53.5	52.5	53.5

Typically the TBP curve and a few of the important physical properties (viscosity, density, cloud and PPs, etc.) of each cut fraction are reported in a standard abbreviated laboratory analysis of a crude. More recently, a generic speciation by carbon number and type (PONA) is routinely reported if the proper spectrophotometric equipment and analyst knowledge are available.

1.3.3 Chemical Analysis of Refinery Products[47,59,62]

Refinery products are divided into two categories, namely are ''virgin'' or ''straight-run'' streams that are derived from pure physical separation from the crude feed, and converted stocks which have been run through one or more thermal or catalytic reactions. Of the conversion reactions, cracking of large molecules into smaller ones is the most common. This category can be subclassified into thermally cracked stocks, catalytically cracked stocks and hydrocracked stocks. Other reactions common in refineries are reforming, isomerization and alkylation.

The major refinery streams of ultimate value in a refinery are virgin naphtha, thermal crackate, catalytic reformate and hydroprocessed stocks.

Compositional comparison charts are illustrated as follows:

- Figure 2 shows typical components in virgin crude cuts.
- Figure 5 shows typical component compositions for a catalytically reformed stock.
- Figure 6 shows typical component compositions for a catalytically cracked stock.
- Figure 7 shows typical component compositions for a hydrocracked stock.

Catalytic reformate contains the largest amount of aromatics, which increase the octane rating. Thermal crackate made from thermal cracking or coking processes contains significant amounts of olefins which are not stable and thus not suitable as a gasoline component. Virgin naphtha (straight-run naphtha) contains small amounts of aromatics but significant amounts of paraffins.

Figure 1 Sample crude oil composition.

Figure 2 Relative amounts of hydrocarbons in a crude oil.

Figure 3 Typical distillation curves. EFV, equilibrium flash vaporization.

1.3.4 Chemical Analysis of Synfuel Products[57,72,73,142]

Most work on hydrocarbons has gone into products derived from crude oil refineries. There is, however, a significant base of stocks derived from shale oil, coal and heavy oil/tar sands recovery processes.

These stocks contain most of the same chemical components as do petroleum-based derivatives but will also contain substantial amounts of several biaromatic multi-ringed components that are not generally major components of the petroleum-based stocks. They tend to have higher nitrogen levels than most crudes and perhaps a slightly lower sulfur content. A partial listing of some of these chemicals is presented in Table 5.

1.3.5 Component Effects on Refinery Products

1.3.5.1 Motor Gasolines Volatility characteristics for motor performance are dependent upon the amount of lighter components such as butane and pentane. Antiknock characteristics are highly dependent upon the components of the stock involved, especially in the C_6-C_9 range.

1. *Paraffins*: octane number increases with increasing MW and branchedness.
2. *Olefins*: octane number is better than that of corresponding (same carbon number) paraffins.
3. *Naphthenes*: have moderate octane numbers.
4. *Aromatics*: have excellent octane numbers but poor volatility and have some toxic characteristics that have resulted in some regulatory constraints on their usage levels in transportation fuels.

1.3.5.2 Other Petroleum Stocks A lowering of aromatic content generally increases (improves) the SP.

The paraffin content correlates with FRP, CP and PPs of several fuel stocks. Lowering the amounts of paraffins and especially isoparaffins generally improves (lowers) these three property values.

The higher the Watson *K* factor, the higher is the paraffinicity; the lower the Watson *K* factor, the higher is the aromatics content.

Highly paraffinic crude oils may deposit waxes in transport lines and processing equipment. On the other hand, the lube oils made from these stocks are generally of superior quality.

Highly aromatic or naphthenic stocks will tend to form more coke in cracking and pyrolysis operations. They may also tend to foul catalyst pellet matrixes in various conversion processing operations.

Table 6 shows a series of gasoline blend components and a select set of their corresponding properties.

2 HYDROCARBON CHARACTERIZATION FROM DISTILLATION CURVES

2.1 Introduction

Hydrocarbon fractions, being a mix of several dozen to hundreds of hydrocarbon compounds, cannot be treated simply as a single pure component. A measure of the various molecular sizes is necessary in order to obtain meaningful thermodynamic information about the cut. The typical measure of molecular size distribution is via a volumetric distillation designed to measure the ''true'' molar boiling point of each incremental volume of overhead batch distillate. These boiling points, combined with corresponding cut point gravities, are used to estimate MWs. Nearly all industrial hydrocarbon characterization procedures require at least two of these quantities.

One more reason why this makes sense is that hydrocarbon cuts are usually separated in the refinery on the basis of distillation column performance. The boiling point range of a cut is highly dependent upon the size of the molecules, as are the subsequent properties of the fraction stream. Since the boiling point of each familiar homolog of components rises in a predictable fashion with size (i.e. MW), the boiling temperature of a cut indicates something about the relative size of the molecules in the

Figure 4 Product yields on TBP curve.

cut and their subsequent expected behavior. Typically, the hundreds of component species in a cut are ''lumped together'' on the basis of comparable boiling points for simplicity. This is why establishing the average ''true'' boiling point of a cut/fraction is so important. One can also then understand that the smaller the cut range, the more likely one is to be able to use these boiling-point lumping models (also called pseudocomponents or hypotheticals) with any reasonable accuracy.

There are numerous ways of using distillation curves to characterize hydrocarbon fractions. No particular purpose would be served by attempting to present all these methods here. Instead, only those considered most reliable and useful will be included.

2.2 Generation of Distillation Curves

There are four primary types of laboratory distillation curves that are used to characterize crude oils and refinery products, and these curves constitute the most important and useful information upon which the process design engineer must rely. Of these, the most useful curve is the true boiling point (TBP) curve. TBP values are rarely a final product specification but these values are most useful in extrapolating properties of various cuts within the measured TBP cut range.

1. The TBP distillation is basically a batch distillation conducted in equipment of high fractionation efficiency, such that each increment of overhead vapor is (theoretically) a pure component at its TBP. The curve is a plot of overhead temperature versus cumulative volume percentage overhead yield. A sample TBP–volume % overhead curve for a full range crude is shown in Figure 3.

   One consistency problem here is the lack of a real standard procedure for conducting a TBP test. ASTM D-2892 is a standard that is often used, but most laboratories modify it for various reasons. Since the various laboratory stills in use employ

Figure 5 Composition of catalytic reformate vs. thermal reformate and straight-run charge (Pennsylvania crude).

Figure 6 Catalytic cracker naphtha compositions.

different numbers of trays and different reflux ratios, a particular oil sample will yield slightly different TBP curves depending on where the distillation is run.

The terms ''Oldershaw'', ''Podbielniak'', ''Hypercal'' and ''15/5'' (15 trays, 5:1 reflux ratio) refer to distillations that are essentially TBP runs.

The United States Bureau of Mines (USBM) historically used the ''Hempel'' distillation for its crude assay work.[80] The Hempel distillation, and the very similar ASTM D-285, are what may be termed semifractionating distillations. Both of these procedures give some degree of fractionation, but are less efficient than a TBP distillation and should not be regarded as truly equivalent to TBP runs.

2. The newest and most promising methods are based primarily on GC analysis of the crude stream or its fractional cuts. Recent improvements to GC instrumentation allow for direct estimates of TBP based on elution times of component vapor through a chromatographic column. Although limited to 1000 °F boiling points and below, they are quick and reliable. ASTM D-2887 and D-3710 are rapidly becoming laboratory standards.

   Whenever possible, the source of any directly measured TBP distillations should be at least one of the 15/5 or better procedures or the equivalent GC predictive method.

   In some cases, the TBP curve is a derived function from one of two ASTM distillation procedures.

3. The first of these ASTM distillations is covered by ASTM specification D-86 for tests conducted at atmospheric pressure (ATM) for lighter refinery fuel-blend stocks (naphtha, kerosine, light diesel). D-86 values are often a final product specification.

4. The second major ASTM distillation is covered by ASTM specification D-1160 for tests conducted at high vacuum for heavier refinery high-boiling point stocks (heavy diesel, gas-oils, resids, etc.). D-1160 values are often a final product specification.

Figure 7 Composition distribution of gasoline from hydrocracking of typical gas-oil.

Table 5 Component data for coal-based hydrocarbons[108]

Component	MW	API	NBP (°F)	Critical temperature (°F)	Critical pressure (psia)
Phenol	94.1	0.13	359.2	791.5	889.1
Tetralin	132.2	13.84	406.1	834.5	510.0

2.3 Cut Fraction Characterization – Manual Methods

2.3.1 Establishing the True Boiling Point Curve – Methods

The typical means of measuring molecular size distribution is with a volumetric TBP distillation. This is a laboratory-based batch distillation whereby the overhead recovery of a percentage of the initial charge is recorded versus the average temperature of the bottoms in the still pot. The following methods are used in industry today.

2.3.1.1 Distillation via American Society for Testing and Materials D-86 Procedures (Usually at 760 mmHg Pressure) This procedure is used for lower boiling hydrocarbon cuts such as gasoline, kerosines and even some light diesel oils. This test is a batch distillation in which no vapor fractionation occurs, so the the still vapor temperature is theoretically the dewpoint of a continuously changing (increasing in MW and therefore boiling point) hydrocarbon stream. Although not directly related to composition, this test is still a primary test because of its low cost and high degree of standardization and reproducibility. Nearly all fuel product specifications are expressed in terms of a D-86.

2.3.1.2 Distillation via American Society for Testing and Materials D-1160 Procedures (Usually at 10 mmHg Pressure) This procedure is used primarily for higher boiling hydrocarbon cuts such as heavy oils, resids, fractionator bottoms, etc. The typical vacuum conditions provide a pressure at which a significant recovery of material can be obtained without the need to use high temperatures to vaporize. Hydrocarbons start cracking around 316–343 °C (600–650 °F), so the longer the analyst can carry out the distillation under lower temperatures, the more accurate the analysis of the heavy ends in the initial still charge will be.

This test is a batch distillation in which no vapor fractionation occurs, so the still vapor temperature is theoretically the dewpoint of a continuously changing (increasing in MW and therefore boiling point) hydrocarbon stream. Although not directly related to composition, this test is still a primary test because of its high degree of standardization and reproducibility. Nearly all heavy product specifications are expressed in terms of a D-1160.

2.3.1.3 Distillation via Experimental True Boiling Point Procedures TBP distillation is meant to represent the ''true'' molar boiling point of each incremental amount of recovered overhead still product, i.e. if each small amount of distillate liquid were in fact a pure component, its NBP would correspond to the still pot temperature at the time it went overhead. In practice, this cannot occur, but by increasing the fractionation efficiency of the still, the MW distribution of the overhead liquid can be narrowed. In this way, a fairly good estimate of the ''average'' molar boiling point of a distillate cut at a given temperature can be made. The still efficiency is dependent on the number of rectifying plates and the amount of reflux that is used to maintain liquid traffic in the trayed section. Typical TBP columns (Oldershaw and some of the newer systems) use what is known as a 15/5 specification, that is 15 trays with a 5 : 1 reflux ratio. This standard, however, is more traditional than anything, and most TBP cuts are taken under conditions ranging from 5/3 to 60/20, depending upon the equipment and the care taken by the laboratory analyst.

ASTM D-2892 is as close as anything to a standard for this test. It is prescribed only for a full-range crude analysis but should work well for any wide-boiling cut.

2.3.1.4 Distillation via American Society for Testing and Materials D-2887/D-3710 Gas Chromatography Procedures These are newer procedures, based on a GC reconstruction of the boiling point curve, which are quickly becoming the preferred reporting methods for literature and operations data. They are quick and accurate, although the required equipment is somewhat expensive. ASTM procedure D-3710 covers the analysis of stocks with NBPs <260 °C (500 °F). D-2887 theoretically covers a full-range crude but must typically be limited to NBPs <538 °C (1000 °F). Any molecules that are too large are either cracked in the elution column or end up as coke on the column packing.

D-2887 results are often close enough to ''true'' TBP that some laboratories will substitute them directly. Several correlations exist, however, for converting D-2887 values to ''true'' TBPs and D-86 assays, and should be used preferentially.

Data concerning any hydrocarbon fraction will ultimately be obtained in one of the above forms. Occasionally, the curve for mid-range cuts will be reported as a composite, the lower boiling cuts being measured via the D-86 procedure and the higher boiling cuts being reported as D-1160. This protocol is fine as long as the assumptions are made clear in the reported data.

Several laboratory methods today combine a chromatography step with some form of additional downstream analysis of the eluate. Spectral emission is the most common supplemental analysis method, with gas chromatography/infrared (GC/IR) spectroscopy and gas chromatography/mass spectrometry (GC/MS) being the most advanced in terms of broad applicability. High-performance liquid chromatography (HPLC) with hydrodealkylation (HDA) is promising for determining aromatics in 343+ °C (650+ °F) fractions, but is limited for other components and boiling point ranges. This advanced equipment is also expensive and difficult for

all but trained laboratory operators to use. Therefore, its general usage will grow slowly for some time.

2.4 Establishing the True Boiling Point Curve – Where to Start

The normal method of petroleum fraction characterization requires the generation of a TBP curve. Unless measured directly, a fairly time-consuming and costly procedure, a TBP curve must be derived from another form of distillation.

Figure 3 shows typical relationships between an ASTM distillation curve and a TBP distillation curve for a full-range cut. The ASTM curve has had the 371 °C (700+ °F) portion of the curve corrected to 760 mmHg pressure, because its data were taken at 10 mmHg via the D-1160 procedure, but the relationship of the resulting curve to the more tightly separated TBP curve is still valid. The equilibrium flash vaporization (EFV) curve shown on Figure 3 is an EFV curve of the type that used to be an industry standard method for estimating a single-stage ideal flash. With the availability of inexpensive computer software for stage flashes, this particular curve has fallen into general disuse and will not be covered here.

Several methods have evolved for relating the ASTM curves to a TBP curve. The classical graphical procedure based on both the Edmister–Pollock[70] and Edmister–Okamoto[71] methods is illustrated in Figure 8.

Figure 8 ASTM–TBP relationships.[70,71]

These methods are still recommended by the API[9] and are used by refining engineers. Some use one method exclusively but the blend of the two seems to give the most uniform results. Most companies, and the API itself, have provided computer-compatible equations for distillation conversions based on Figure 8 or refinements thereof. A more detailed discussion of these procedures is covered in subsequent sections of this article.

Figure 9 shows the ''preferred'' methodology of the API Technical Data Committee as the solid lines and the author's suggested deviations as the dashed lines. These procedures provide reasonable and consistent answers.

2.5 Quality of Data

The major problem in defining a TBP curve is not so much the manipulation of the data but rather the quality of the data themselves. ASTM distillations are defined by fairly rigid standards and as long as the equipment meets the standard and is run properly (most new analytical units are digitally controlled), the main source of error is the care with which the analyst reports the data. The quality of directly reported TBP curves, however, has error inherent from both the distillation conditions and the method of analysis, in addition to the biases and errors of the analyst.

Since the generation of ''boiling-lumped'' pseudocomponents requires a TBP curve, the real problem becomes one of defining the curve from the ''best-quality'' data. A good analyst with good equipment, generating a ''true'' TBP curve, is the optimum situation. The word ''true'' is in quotes because sometimes reported TBPs are actually ASTM distillations that have been transformed by either the analyst or the apparatus (the newer ones under microchip control). Use of these latter TBP values leaves one at the mercy of the transform method. Any such transformed data should be thoroughly rechecked before use.

Given the existence of a real or assumed TBP curve, the engineer then starts to divide the curve into volume-specific cuts defined by their corresponding segmental end-point temperature. Figure 12(a) and (b) (see later) shows how this might be done.

In any case, the reader must realize that converting from one distillation curve to another is somewhat of an inexact procedure, and errors as great as 17–22 °C (30–40 °F) may occur with wide-boiling stocks. It is essential, therefore, that the chemist or engineer be realistic about the accuracy of estimated distillation curves. This means checking important results by more than one method, and allowing reasonable safety margins so that the overall workability of a design is not jeopardized by unavoidable inaccuracies.

Figure 9 Distillation conversion pathways. Solid lines are API-sanctioned methods. Dashed lines are alternative means of estimation. These may or may not be consistent with conversion results from a different path.

2.6 Methods to Use When Lacking "Total Data"

The above recommendations are dependent upon the existence of some *real* distillation data on the hydrocarbon cuts in question. When such data are not available, the engineer must use judgment and some knowledge about the relative amounts of the various types of components in the stream.

For estimating an ATM tower resid, one may have only a sample of the full-range crude and an idea of the fractional residual. Knowing that most resids (at least those from reasonably efficient fractionation systems) have TBPs starting around 260–288 °C (500–550 °F), one may elect simply to cut off the resid tail of the ''full-range TBP'' at the volume percentage corresponding to the fraction residual and use that as the heavy fraction TBP curve, normalizing the cut fractions to a full 100% basis.

An extension of this line of thinking allows one to specify a full-range cut based on some assumptions about the various parts of that whole stream. One might characterize the effluent of a hydrocracker as consisting of 20 standard vol.-% of light naphtha cuts [32 °C (90 °F) < NBP < 82 °C (180 °F)], 30% heavy naphtha cuts [82 °C (180 °F) < NBP < 196 °C (385 °F)], 40%

of mid-distillate cuts [196 °C (385 °F) < NBP < 287 °C (550 °F)] and the residual.

From these assumptions, a TBP curve for the full cut can be estimated. Although not as accurate as distillation curve analysis, this method will allow the engineer to proceed with work in the absence of ''real'' data.

Typical procedures, assuming the availability of some TBP data, are illustrated in Table 7.

In 1987, the American Petroleum Institute (API)[10] also developed a correlation for interconversion of D-2887 and TBP data. The original intent was to develop the correlation at each ''standard'' volume node (10, 30, 50, 70, 90% points).

In general, the correlation did well except for several diesel–gas-oil range boiling cuts that had a fairly ''flat'' boiling range from the 30–70% range. In such cases, the correlation predicted regressive values of at least one of the 50, 70 or 90% points. This did not go over well in the refining community and the correlation was revised to its current form; see sections 3.12.2.1 and 3.12.2.2 for descriptions. In spite of the problems, it is still an excellent method of predicting TBPs from a very limited amount of data. If one has only 10, 50 and 90% D-86 values (not an uncommon situation), this method may give better results than using interpolations to calculate difference values.

If one must *interpolate* from data not on the ''standard'' reporting volumes nodes, use a quadratic or spline fit procedure. To extrapolate (very carefully – avoid if at all possible!), use a probability plot format. The MWs, and thus the boiling points, of the stream components can be assumed to be normally distributed about a mean value.

Table 7 Construction of full-cut TBP curve

1. If the residual is entirely heavy (>550 °F) material, the TBP will be as follows:

TBP (°F)	Cumulative vol.-% overhead
90	0
180	20
385	50
550	90

2. If the residual is entirely light (<90 °F) material, the TBP curve will be as follows:

TBP (°F)	Cumulative vol.-% overhead
90	10
180	30
385	60
550	100

3. If the residual is partly lights and heavies, the TBP curve, assuming a 2% lights/8% heavies residual ratio as an example, will be as follows:

TBP (°F)	Cumulative vol.-% overhead
90	2
180	22
385	52
550	92

2.7 Establishing the Pseudocomponents

Whereas arrival at a ''final'' TBP curve may be accomplished in several ways, the method of defining pseudocomponents (or commonly called hypotheticals) has less variation.

Petroleum fraction pseudocomponents are traditionally defined in terms of their NBPs. In the simplest method of determination, a certain boiling range of a TBP curve is segregated and the mid-volume boiling temperature is found graphically. In looking at Figure 4, one might define nine pseudocomponents by the heavy cut lines crossing the TBP curve. The components would then be identified as NBP140, NBP316, NBP413, NBP490, NCP557, NBP621, NBP697, NBP794 and finally, NBP1000, as in Figure 4. One could rename them to corresponding celsius, kelvin or any other meaningful scale for tracking purposes.

This last mid-range temperature is estimated from an assumed end-point for the heavy end of the curve. It is most difficult to measure the boiling points of heavy resids, as they tend to be destroyed (cracked) in the process of having their boiling point measured. Unfortunately, this lack of a definable end-point is a major source of error in the characterization of resid fractions. One can use some advanced interpolation methods (details of which are beyond the scope of this article) to aid in end-point estimates, but even these are only of marginal value. It should also be noted that MW correlations based on NBP and gravity become increasingly inaccurate for higher boiling point material.

Using the classical TBP cut method of determining pseudocomponents has its limitations in heavy resid processing.

2.8 Calculation of the Average Cut Parameters

Once the TBP range for the pseudocomponent has been defined, the calculation of MW and related parameters can commence. Nearly all correlations require the NBP and specific gravity (SG) of a cut. Some use these two parameters completely separately and some incorporate the SG in a Watson K (K_W) parameter. Implicit with any TBP curve is a related gravity versus volume fraction curve or a gravity–boiling point curve.

In general, the SG of the overhead product increases as the distillation progresses (i.e. as both volume-% and/or distillation temperature increase). In many instances, the SG curve is reported along with the temperature curve. This is the ideal situation, in that all quantities necessary to define the MW are specified.

Usually just the average whole-stream gravity is reported. In this case, the best procedure is to estimate the individual pseudocut gravities based on some idea of what the SG of the cut does with increasing NBP.

Figure 10 shows a typical representation of a straight-run cut SG–volume-% curve and one of a "cracked" fraction. Both are monotonic, with a constantly increasing dependent function value. The cracked fraction, however, has an inflection point (where the second derivative changes).

Figure 11 shows a typical representation of cut fraction K_W–vol.-% curves for several different hydrocarbon stream types. The characteristic of most interest to refiners is the fact that for thermally cracked and hydrocracker effluents, the K_W of the mid-distillate material tends to be low in comparison with the tails. The explanation for this is fairly simple. K_W is strongly correlated with the degree of paraffinicity and inversely correlated with the degree of aromaticity in a fraction. Most hydrocracking forms paraffinic products, highly saturated although often highly branched. The hydrocracking process and reforming processes also produce a large number of single-ring aromatic compounds with boiling points in the region of kerosine and light diesel with a corresponding reduction in average K_W in this area. In most straight-run fractions, by contrast, the lightest components tend to be paraffinic and the heavy components are more aromatic and naphthenic, giving a continually decreasing K_W vs volume percentage curve.

Defining cut gravity in the absence of real data depends chiefly upon how the variation of the K_W is perceived. For straight-run crudes, the assumption of a constant K_W, based on either the cut-point TBP (preferred by most of the industry) or ASTM-D-2887 mid-point temperature, is the usual method. The engineer, however, knowing something about the true K_W curve, may want to make some educated guesses about the local variations from this assumption.

A few comments should be made with respect to Figure 11. The curves are typical for shape only. Actual plot values are dependent upon the stream and can vary greatly from those shown. Within whole crude cut fractions, constant K_W is not a bad assumption, especially for straight-run fractions. For hydrocracked cuts, it may be invalid since aromatics accumulation from the conversion process tends to build up in the middle distillate range. Crude light straight run (LSR) tend to be more paraffinic on average than the whole crude. This generalization also holds for full-range hydrocracker effluents. Highly paraffinic crudes also have a region of increasing K_W but it tends to start with 650 °F+ NBP material and the change is not as pronounced as with the mid-range hydrocracker effluents. In the case of hydrocracker effluents, the double-inflected curve in Figure 11 may be a more appropriate type to follow.

2.9 Measures of "True" Boiling Point

Once the NBP and SG of a cut have been set, the MW can be obtained in a straightforward fashion. Details of the best current methods of calculating hydrocarbon cut fraction MWs are discussed in section 3 and will not

Figure 10 API gravity vs distillation volume-% (ASTM, TBP, etc.). The fractions are of identical average gravity but are not necessarily related by any other means. Curves are for illustrative purposes only. , Typical straight-run cut; +, typical cracked cut.

Figure 11 K_W vs distillation volume-% (ASTM, TBP, etc.). , Highly paraffinic crudes; +, typical full-range R-2 effluent; ○, naphthenic crude 1; △, naphthenic crude 2.

be repeated in any great detail here. What is of some controversy is just what the NBP measures. In any cut, there are several measures of a mean boiling temperature.

There is the volumetric average boiling point (VABP), which is *not* identical with the mid-boiling point temperature (see Figure 12a and b), the CABP, which is the theoretical basis for K_W calculations, the MABP (defined in Figure 12a and b) and the MEABP, which the API defines as the average of the CABP and the MABP. These values are outlined graphically in Figure 12(a) and (b) and explained as numerical approximations below.

Several methods typically used by oil companies and process engineering contractors use the VABP, a very simple number to generate or estimate. The Twu[142] correlation used in some process simulation packages such as ''Process/Provision'' uses MABP, and the most recent correlation approved by the API Technical Data Committee uses MEABP, as did earlier versions of their methodology.

Note that for narrowly defined TBP temperature cuts, all these measures of ''average'' boiling point tend to converge. It is only when trying to characterize a wide-boiling fraction that the differences in the NBP values become significant. An exception is in the use of mid-range boiling points for the front and back ends of a cut (i.e. the 0–10 and 90–100% ranges). The mid-range value in these cases can be significantly lower than the VABP (5% vs 7% on a steeply sloped curve). An extra effort should be made to define the VABP better for these tail cuts.

The five primary boiling point vectors can be estimated by algebraic means, given a defined mixture. The temperature units of the first three distillation data functions do not matter as long as they are consistent with each other and with that of the calculated average value. The quantities are defined by Equations (5–8):

$$\text{VABP} = \text{SUM}[V_i \times Tb_i] \tag{5}$$

$i = 1 \rightarrow$ No. of components, where VABP is the volumetric average boiling point, V_I is the volume fraction of component i, and Tb_i is the NBP of the ith component;

$$\text{MABP} = \text{SUM}[X_i \times Tb_i] \tag{6}$$

$i = 1 \rightarrow$ No. of components, where MABP is the molar average boiling point, X_i is the volume fraction of component i and Tb_i is the NBP of the ith component;

$$\text{WABP} = \text{SUM}[W_i \times Tb_i] \tag{7}$$

$i = 1 \rightarrow$ No. of components, where WABP is the weight average boiling point, V_i is the volume fraction of component i and Tb_i is the NBP of the ith component;

$$\text{CABP} = \text{SUM}[V_i \times Tb_i^{1/3}]^3 \tag{8}$$

$i = 1 \rightarrow$ No. of components, where CABP is the cubic average boiling point, V_i is the volume fraction of component i and Tb_i is the NBP of the ith component.

The temperature of the distillation data for Equation (8) must be absolute (in either degrees rankine or kelvin) and must be consistent with each other and with that of the calculated average value.

$$\text{MEABP} = \frac{\text{MABP} + \text{CABP}}{2} \tag{9}$$

where MEABP is the volumetric average boiling point and CABP and MABP are defined as above.

The temperature of the three distillation averages must be consistent with each other. MEABP is typically considered to be the best approximation for the NBP of a cut and, if available, is the temperature of preference. For narrow cuts, however, all of the values should converge within a few degrees of each other.

Given the fact that full-range analyses of crudes and fractions of crudes are time-consuming and costly, the API has developed the following correlations for a broad boiling range hydrocarbon.

From D-86 distillation data, find the VABP with five standard cut values (Equation 10):

$$\text{VABP} = \frac{T_{10} + T_{30} + T_{50} + T_{70} + T_{90}}{5} \tag{10}$$

If data are scarce and a calculation has to be made, one could use (as have some) Equation (11):

$$\text{VABP} = \frac{T_{10} + T_{50} + T_{90}}{3} \tag{11}$$

The author feels, however, that it would be better to intuitively estimate a T_{30} and a T_{70}, then use Equation (10).

The VABP and subsequent ''average'' derivation methods can also be used with TBP curves, provided that they are identified as such, and that a corresponding D-86 vector has been established corresponding to the TBP curve. Often the D-86 and TBP distillation averages are used interchangeably (and improperly) by novices. The primary reason why the D-86 values need be present is for calculating 10–90% slopes (Equation 12):

$$SL_{1090} = \frac{T_{90} - T_{10}}{90 - 10} \tag{12}$$

The other assay average parameters are calculated according to Equations (13–24):

$$\text{WAPB} = \text{VABP} + \text{Temp_diff_wt} \tag{13}$$

Figure 12 Determination of (a) volume average NBP and (b) molar average NBP. The Watson K uses the cubic average boiling point, $\text{CABP} = \sqrt[3]{\int \text{VABP}^3 \, dV \quad dV}$. Most MW correlations use the molar average boiling point, MABP. 1988/91 API revised correlations use the mean average boiling point, MEABP, which is the average of the cubic and molar average boiling points, $\text{MEABP} = (\text{CABP} + \text{MABP})/2$.

Figure 13 (a) Boiling point conversion chart; (b) Watson K (K_W) correction for (a). Note the logarithmic abscissa in (b).[9,97]

where Temp_diff_wt is determined by Equation (14):

$$\ln(\text{Temp_diff_wt}) = -3.062 - 0.01829(\text{VABP} - 32)^{0.6667} + 4.458SL_{1090}^{0.25} \quad (\text{units of } ^\circ\text{F}) \tag{14}$$

$$\ln(\text{Temp_diff_wt}) = -3.649 - 0.0271(\text{VABP})^{0.6667} + 5.614SL_{1090}^{0.25} \quad (\text{units of } ^\circ\text{C}) \tag{15}$$

$$\text{MABP} = \text{VABP} - \text{Temp_diff_mo} \tag{16}$$

where Temp_diff_mo is determined by Equation (17):

$$\ln(\text{Temp_diff_mo}) = -0.5638 - 0.007981(\text{VABP} - 32)^{0.6667} + 3.047SL_{1090}^{0.3334} \quad (\text{units of } ^\circ\text{F}) \tag{17}$$

$$\ln(\text{Temp_diff_mo}) = -1.152 - 0.01181(\text{VABP})^{0.6667} + 3.707SL_{1090}^{0.3334} \quad (\text{units of } ^\circ\text{C}) \tag{18}$$

$$\text{CABP} = \text{VABP} - \text{Temp_diff_cu} \tag{19}$$

where Temp_diff_cu is determined by Equation (20):

$$\ln(\text{Temp_diff_cu}) = -0.2359 - 0.0691(\text{VABP} - 32)^{0.45} + 1.886SL_{1090}^{0.45} \quad (\text{units of } ^\circ\text{F}) \tag{20}$$

$$\ln(\text{Temp_diff_cu}) = -0.8237 - 0.08997(\text{VABP})^{0.45} + 2.457SL_{1090}^{0.45} \quad (\text{units of } ^\circ\text{C}) \tag{21}$$

$$\text{MEABP} = \text{VABP} - \text{Temp_diff_nbp} \tag{22}$$

Table 8 Comparison of boiling point averages of four different cuts at different VABPs

VABP (°C)	Engler slope (°C %$^{-1}$)	Type of boiling point	Value from chart (°C)	Calculated value (°C)
100	2.0	WABP	106.3	106.7
200	0		200.0	200.0
300	2.8		306.3	306.2
400	5.0		414.6	413.5
100	0.5	MABP	95.1	95.4
200	2.3		172.5	171.9
300	0.8		293.9	294.2
400	3.0		364.9	365.1
100	1.0	CABP	97.4	97.5
200	1.3		197.2	197.4
300	3.8		288.0	288.0
400	2.0		396.8	396.7
100	0.3	MEABP	98.0	98.1
200	3.3		167.7	168.2
300	1.8		290.1	289.7
400	4.0		364	364.7

where Temp_diff_nbp is determined by Equation (23):

$$\ln(\text{Temp_diff_nbp}) = -0.9440 - 0.00865(\text{VABP} - 32)^{0.6667} + 2.998SL_{1090}^{0.3334} (\text{units of } ^\circ\text{F}) \tag{23}$$

$$\ln(\text{Temp_diff_nbp}) = -1.532 - 0.0128(\text{VABP})^{0.6667} + 3.617SL_{1090}^{0.3334} (\text{units of } ^\circ\text{C}) \tag{24}$$

Table 8 shows a comparison of these boiling point averages of four different cuts at different VABPs.[157]

2.10 Measures of Fractionation Efficiency

Distillation assays can have value within themselves. Fractionation performance in crude units and other refinery fractionators is commonly specified as a targeted distillation value to be achieved, such as a D-2887 (90%) value maximum for CARB (California Air Resources Board) gasoline, though this latter method is more often used to set draw rates. A pure measure of column fractionating capacity is often gaged as the *difference* between the ASTM 5% point of a product and the ASTM 95% point of the next lighter product. This ''gap'' is defined according to Equation (25):

$$\text{gap} = \text{heavy curve D86}_{5\%} - \text{lighter curve D86}_{95\%} \tag{25}$$

A high degree of fractionation will result in the 5% point being higher than the 95% point, producing a so-called positive ''gap'' value. Poor fractionation, on the other hand, will result in an overlap where the 95% point is actually higher than the 5% point, or a negative ''gap''. The required fractionation performance is generally specified by the process engineer and is generally higher for the lighter product cuts unless the column has some mechanical problems.

Gaps of 17–28 °C (30–50 °F) are commonly found between naphtha (gasoline) cuts and kerosine or between kerosine and light diesel. Gaps of 0 to −11 °C (0 to −20 °F) are more common between heavier cuts. Figure 14(a–c) illustrates this situation for a full-range crude.

Note that if the fractionation is perfect, the TBP curves of the cuts form a complete unbroken curve that is identical with the TBP curve of the fractionator feed. Perfect fractionation, however, is never achieved in commercial side-draw columns. Some of the heavier product is unavoidably withdrawn with the lighter product and vice versa, thus forming the ''tails'' shown in Figure 14(b). The poorer the degree of fractionation, the greater will be the deviations of the TBP tails from the feed TBP curve, and consequently the greater will

Figure 14 Degrees of fractionation: (a) perfect, (b) good and (c) poor fractionation.[150]

be the deviations of the respective ASTM curves until, eventually, overlap of the adjacent ASTM and TBP 5/95 curve values occurs.

2.11 Interconversion of Distillation Data[9–15]

2.11.1 Introduction

The general use of the TBP (and other) distillation curves as part of the characterization process for cut analyses has been covered to this point. The major focus of this section is to enable the chemist or engineer to arrive at an ATM TBP curve for a stock, particularly from data that were derived from an ASTM standard test. From these data, several other curves and physical properties can be estimated with good accuracy. Very often, these methods can be used (usually with some mathematical manipulation) to impute various inspection data in hydrocarbon streams.

The most important thing to realize is that converting from one distillation curve to another is a rather inexact procedure. Errors as great as 17–22 °C (30–40 °F)

may occur with wide-boiling stocks. It is essential, therefore, that the engineer be realistic about the accuracy of estimated distillation curves. This means checking important results by more than one method, and allowing reasonable safety margins so that the overall workability of a design or analysis dependent upon this data is not jeopardized by unavoidable inaccuracies in the correlations.

Several methods for converting one distillation curve to another are presented in this section. Most are currently recommended by the API Technical Data Committee, the premier nonconfidential information source currently available for hydrocarbon stock thermodynamics. A few are useful correlations that the author has used for this type of work.

In general, for converting an ASTM curve to a TBP curve (or vice versa), Edmister's methods (as shown in Figure 8) and its recent empirical derivatives are generally recommended.

The classical correlation for 50% point ASTM $\rightleftharpoons$ TBP is based on work by Edmister and Pollack[70] in 1948 and is considered by the API to be superior to a later correlation published by Edmister and Okamoto[71] in 1958. In using Figure 8, the 50% point temperature of the required curve is determined from the 50% point of the known curve. A recent API correlation for this graphical method has been published, where the 10, 30, 50, 70 and 90 vol.-% points are known on one or the other side. This method is probably the most accurate available procedure, assuming that one has enough data.

Since most refineries and petrochemical plants try to get by with the minimum amount of expensive on-line analyzers, these methods are well tested.

In a few cases, an analyzer will only report one or two specific volume-% points. Sometimes the residual portions of the distillation curve cannot be obtained. For these situations, one can use an older API correlation based on inter-conversion from one corresponding volume-% directly to that of the target curve, without assuming knowledge of the rest of the source or target value curves. There are some caveats that the user must observe. Trying to construct a full-range curve from the point method can lead to problems, which will be described in detail below. If one is able to generate reliably a full-range ASTM or TBP distillation, the full-range methods should be used.

In any event, this correlation has been useful to the author and can be utilized as a check on the values derived from the other methods.

2.11.2 Physical Distillation Conversion Procedures

The most recent revisions of the API Technical Data Book (1987–98) contain several useful procedures for interconversion of "standard" mixed-hydrocarbon distillation curves.

Figure 9 (solid lines) shows the 1994 API recommended conversion pathways for constructing one curve type from another. An explanation of these procedures, or their acceptable alternatives (dashed lines), follows.

2.11.2.1 Interconversion of American Society for Testing and Materials D-86 and True Boiling Point Distillation Curve at Atmospheric Pressure Full Range Assay[9]

This method should be used only for a fully defined assay of a stream. Trying to derive a full TBP curve from three or more such point applications of this method can create problems.

Equations (26) and (27) are used to interconvert ASTM D-86 and ATM TBP distillation data:

$$\text{TBP}_{50\%} = a(\text{ASTM D-86}_{50\%})^b \tag{26}$$

$$\text{ASTM D-86}_{50\%} = \left(\frac{\text{TBP}}{a}\right)^{1/b} \tag{27}$$

where $a = 0.8718$ and $b = 1.026$ for the interconversion of the 50% points, TBP temperatures at 0, 10, 30, 50, 70, 90 and 95 vol.-% distilled, in degrees Rankine, and ASTM D-86 = observed ASTM D-86 temperatures at the corresponding volume-% distilled, in degrees Rankine.

The procedure works by calculating differential temperatures from the mid-volume boiling point value and translating that value to the other corresponding member of the pairing.

The difference between adjacent cut points can be determined from a series of equations for each interval (Equation 28):

$$\text{TBP_diff(I)} = C_0(\text{D-86_diff})^{C_1} \tag{28}$$

where C_0 and C_1 are coefficients for varying temperature ranges, TBP_diff( ) and D-86_diff( ). Their vectors are shown in Table 9. Temperature values and differences must be in consistent units.

To determine the TBP values at any percentage distilled, add or subtract the proper differentials from

Table 9 Coefficients for ASTM D-86–TBP conversion

Difference vector index value	Cut point range (vol.-%)	C_0	C_1
1	100–90	0.1180	1.661
2	90–70	3.042	0.750
3	70–50	2.528	0.820
4	50–30	3.031	0.8008
5	30–10	4.900	0.7164
6	10–0	7.401	0.6024

the predicted 50% TBP temperature (Equations 29–34):

$$\mathrm{TBP}_{0\%} = \mathrm{TBP}_{50\%} - \mathrm{TBP_diff}(4) - \mathrm{TBP_diff}(5) - \mathrm{TBP_diff}(6) \quad (29)$$

$$\mathrm{TBP}_{10\%} = \mathrm{TBP}_{50\%} - \mathrm{TBP_diff}(4) - \mathrm{TBP_diff}(5) \quad (30)$$

$$\mathrm{TBP}_{30\%} = \mathrm{TBP}_{50\%} - \mathrm{TBP_diff}(4) \quad (31)$$

$$\mathrm{TBP}_{70\%} = \mathrm{TBP}_{50\%} + \mathrm{TBP_diff}(3) \quad (32)$$

$$\mathrm{TBP}_{90\%} = \mathrm{TBP}_{50\%} + \mathrm{TBP_diff}(3) + \mathrm{TBP_diff}(2) \quad (33)$$

$$\mathrm{TBP}_{100\%} = \mathrm{TBP}_{50\%} + \mathrm{TBP_diff}(3) + \mathrm{TBP_diff}(2) + \mathrm{TBP_diff}(1) \quad (34)$$

To determine calculated ASTM D-86 values from measured TBP values, reverse the procedure.

2.11.2.2 Interconversion of American Society for Testing and Materials D-86 and True Boiling Point Distillation Curve at Atmospheric Pressure with Only Three or Fewer Points[10] This method should be used only for point-to-point conversions when no better range of data is available. Trying to derive a full TBP curve from three or more such point applications of this method can create problems. Distillation curves, by definition, are monotonic functions increasing with temperature. In some cases one sees a fairly flat mid-range curve (little temperature increase between the ranges of, for example, 30–40 and 60–70% – a common occurrence with many hydroprocessed stocks and some resid/bottoms streams. These correlations have yielded, on occasion, a distillation curve with the 50 or 70% points equal to or below the corresponding 30% or 50% values. This, of course, is not acceptable. Use this correlation with some care.

Equations (35) and (36) cover point-to-point interconversion of ASTM D-86 and ATM TBP distillation data:

$$\mathrm{TBP} = a(\mathrm{ASTM\ D\text{-}86})^b \quad (35)$$

$$\mathrm{ASTM\ D\text{-}86} = \left(\frac{\mathrm{TBP}}{a}\right)^{1/b} \quad (36)$$

where a and b are constants varying with the percentage of liquid sample distilled as given in Table 10.

2.11.2.3 Interconversion of American Society for Testing and Materials D-1160 Data and True Boiling Point (10 mmHg) Data[9] D-1160 is a common ASTM procedure for distilling heavy stocks whose final boiling temperatures at ATM pressure are well above the cracking initiation temperatures of 316–343 °C (600–650 °F). The presence of a significant amount of cracked products in the outflow of the unit will skew the curve erroneously. A 10 mmHg pressure in the still will safely allow the analysis of stocks that ordinarily could not be measured with ATM equipment. The methodology here is based on API Technical Data Book Procedure 3A2.1, which is the classical Edmister–Okamoto method. Figure 15 is a graphical representation of this method.

Table 10 Coefficients for alternative D-86 TBP conversion (Equations 35 and 36)[a]

Volume-% distilled	*a*	*b*
0	0.9167	1.0019
10	0.5277	1.0900
30	0.7429	1.0425
50	0.8920	1.0176
70	0.8705	1.0226
90	0.9490	1.0110
95	0.8008	1.0355

[a] TBP: TBP temperatures at 0, 10, 30, 50, 70, 90 and 95 vol.-% distilled are in degrees Rankine. ASTM D-86: observed ASTM D-86 temperatures at corresponding volume percentage distilled, in degrees Rankine.

The $T(50)$, $T(70)$, $T(90)$ and $T(\mathrm{EP})$ of the TBP 10 mmHg and D-1160 curves are assumed to be identical by convention. No interconversion is necessary for them.

Warnings/caveats. Many people make the mistake of assuming that the $T(50)$, $T(70)$, $T(90)$ and $T(\mathrm{EP})$ of the TBP 760 mmHg curve and D-1160 10 mmHg curve are identical by convention. Pressure interconversion

Figure 15 ASTM D-1160–TBP (10 mmHg) data interconversion.

between curve types must be done for corresponding cuts at identical pressures. Pressure corrections can be routinely applied before or after the fact to initial data or derived intermediate values, to yield the final curve. The procedure for this is as follows:

1. Calculate the D-1160 $T(30)$ to $T(50)$ difference (units of °F): Given (Equation 37)

$$\text{TBP_diff}(1) = \text{TBP10}(50) - \text{TBP10}(30) \quad (37)$$

then (Equation 38)

$$\begin{aligned}\text{D-1160_diff}(1) &= \text{D-1160}(50) - \text{D-1160}(30)\\ &= -6.993 \times 10^{-2} + 1.354\text{TBP_diff}(1)\\ &\quad - 2.481 \times 10^{-3}\text{TBP_diff}(1)^2\\ &\quad + 5.894 \times 10^{-6}\text{TBP_diff}(1)^3\\ &\quad - 4.780 \times 10^{-9}\text{TBP_diff}(1)^4 \quad (38)\end{aligned}$$

2. Calculate the D-1160 $T(10)$ to $T(30)$ difference (units of °F): Given (Equation 39)

$$\text{TBP_diff}(2) = \text{TBP10}(30) - \text{TBP10}(10) \quad (39)$$

then (Equation 40)

$$\begin{aligned}\text{D-1160_diff}(2) &= \text{D-1160}(30) - \text{D-1160}(10)\\ &= -6.993 \times 10^{-2} + 1.354\text{TBP_diff}(2)\\ &\quad - 2.481 \times 10^{-3}\text{TBP_diff}(2)^2\\ &\quad + 5.894 \times 10^{-6}\text{TBP_diff}(2)^3\\ &\quad - 4.780 \times 10^{-9}\text{TBP_diff}(2)^4 \quad (40)\end{aligned}$$

3. Calculate the D-1160 $T(\text{IP})$ to $T(10)$ difference (units of °F): Given (Equation 41)

$$\text{TBP_diff}(3) = \text{TBP10}(10) - \text{TBP10}(\text{IP}) \quad (41)$$

then (Equation 42)

$$\begin{aligned}\text{D-1160_diff}(3) &= \text{D-1160}(10) - \text{D-1160}(\text{IP})\\ &= -3.896 \times 10^{-2} + 2.315\text{TBP_diff}(3)\\ &\quad - 1.650 \times 10^{-2}\text{TBP_diff}(3)^2\\ &\quad + 5.977 \times 10^{-5}\text{TBP_diff}(3)^3\\ &\quad - 4.735 \times 10^{-8}\text{TBP_diff}(3)^4 \quad (42)\end{aligned}$$

To determine the D-1160 values at any percentage (besides 50%) distilled, add or subtract the proper differentials from the predicted 50% D-1160 temperature (Equations 43–45) (the units in these equations must be consistent with one another):

$$\begin{aligned}\text{D-1160}_{0\%} &= \text{D-1160}_{50\%} - \text{D-1160_diff}(1)\\ &\quad - \text{D-1160_diff}(2) - \text{D-1160_diff}(3) \quad (43)\end{aligned}$$

$$\begin{aligned}\text{D-1160}_{10\%} &= \text{D-1160}_{50\%} - \text{D-1160_diff}(1)\\ &\quad - \text{D-1160_diff}(2) \quad (44)\end{aligned}$$

$$\text{D-1160}_{30\%} = \text{D-1160}_{50\%} - \text{D-1160_diff}(1) \quad (45)$$

2.11.2.4 Conversion of True Boiling Point Data to/from American Society for Testing and Materials D-1160 Data

1. Calculate the TBP $T(30\%)$ to $T(50\%)$ difference (units of °F): Given (Equation 46)

$$\text{D-1160_diff}(1) = \text{D-1160}(50\%) - \text{D-1160}(30\%) \quad (46)$$

then (Equation 47)

$$\begin{aligned}\text{TBP_diff}(1) &= \text{TBP10}(50\%) - \text{TBP10}(30\%)\\ &= 2.416 \times 10^{-1} + 6.940\text{D-1160_diff}(1)\\ &\quad + 1.813 \times 10^{-3}\text{D-1160_diff}(1)^2\\ &\quad - 3.299 \times 10^{-6}\text{D-1160_diff}(1)^3\\ &\quad + 1.692 \times 10^{-9}\text{D-1160_diff}(1)^4 \quad (47)\end{aligned}$$

2. Calculate the TBP $T(10\%)$ to $T(30\%)$ difference (units of °F): Given (Equation 48)

$$\text{D-1160_diff}(2) = \text{D-1160}(50\%) - \text{D-1160}(30\%) \quad (48)$$

then (Equation 49)

$$\begin{aligned}\text{TBP_diff}(2) &= \text{TBP10}(30\%) - \text{TBP10}(10\%)\\ &= 2.416 \times 10^{-1} + 6.940\text{D-1160_diff}(2)\\ &\quad + 1.813 \times 10^{-3}\text{D-1160_diff}(2)^2\\ &\quad - 3.299 \times 10^{-6}\text{D-1160_diff}(2)^3\\ &\quad + 1.692 \times 10^{-9}\text{D-1160_diff}(2)^4 \quad (49)\end{aligned}$$

3. Calculate the TBP $T(\text{IP})$ to $T(10\%)$ difference (units of °F): Given (Equation 50)

$$\text{D-1160_diff}(3) = \text{D-1160}(10\%) - \text{D-1160}(\text{IP}) \quad (50)$$

then (Equation 51)

$$\begin{aligned}\text{TBP_diff}(3) &= \text{TBP10}(10\%) - \text{TBP10}(\text{IP})\\ &= -7.314 \times 10^{-3} + 0.5368\\ &\quad \times \text{D-1160_diff}(2) - 2.899\\ &\quad \times 10^{-3}\text{D-1160_diff}(2)^2 + 5.452\\ &\quad \times 10^{-5}\text{D-1160_diff}(2)^3 - 9.622\\ &\quad \times 10^{-9}\text{D-1160_diff}(2)^4 \quad (51)\end{aligned}$$

The $T(50\%)$, $T(70\%)$, $T(90\%)$ and $T(\mathrm{EP})$ of the TBP and D-1160 are assumed identical by convention. The units in Equations (52–54) must be consistent with one another.

$$\mathrm{TBP}_{0\%} = \mathrm{TBP}_{50\%} - \mathrm{TBP_diff}(1) - \mathrm{TBP_diff}(2) - \mathrm{TBP_diff}(3) \quad (52)$$

$$\mathrm{TBP}_{10\%} = \mathrm{TBP}_{50\%} - \mathrm{TBP_diff}(1) - \mathrm{TBP_diff}(2) \quad (53)$$

$$\mathrm{TBP}_{30\%} = \mathrm{TBP}_{50\%} - \mathrm{TBP_diff}(1) \quad (54)$$

2.11.2.5 Correcting True Boiling Point to Atmospheric Pressure The following method, based on the Maxwell–Bonnell[9] boiling point conversion, API Procedure 3A4.1/Figure 5A19.1, is probably the most utilized correlation in refinery methods and data analysis. ATM boiling points are the starting point for so many correlations.

This method works well only for actual TBP data at any pressure or for ASTM D-1160 subatmospheric to 10 mmHg data. Some people will try to use it to correct ASTM distillations as well. It is not as accurate this way, although it may give reasonable results. For interconversions of other distillation types, one should use the conversion protocol of Figure 9, which forces the pressure calculation into the TBP realm.

The chart upon which this method is based is provided in equation form below.

Distillation Pressure Interconversion – Numerical Method. For subatmospheric to atmospheric conversion, given a volume-%, a subatmospheric distillation temperature and a K_W (either known or estimated), find the ATM cut point temperature via one of Equations (55–57):

Define

$$\log p^* = \frac{3000T' - 6.762}{43T' - 0.9877} \quad (55)$$

when $T' > 0.0022$ ($p^* < 2$ mmHg).

Define

$$\log p^* = \frac{2663T' - 5.994}{95.76T' - 0.9725} \quad (56)$$

when $0.0013 < T' < 0.0022$ ($2\,\mathrm{mmHg} < p^* < 760\,\mathrm{mmHg}$).

Define

$$\log p^* = \frac{2770T' - 6.413}{36T' - 0.9897} \quad (57)$$

when $T' < 0.0013$ ($p^* = 760$ mmHg).

In these equations, p^* = vapor pressure (mmHg), T' is given by Equation (58):

$$T' = \left(\frac{T_{\mathrm{b;\,atmos}}}{T_{\mathrm{b;\,non\text{-}atmos}}} - 0.0002867(T_{\mathrm{b;\,atmos}}\right) \quad (58)$$

$T_{\mathrm{b;\,atmos}}$ = atmospheric cut-point temperature corrected to $K_W = 12$, in degrees Rankine, and $T_{\mathrm{b;\,non\text{-}atmos}}$ = non-atmospheric cut-point temperature, in degrees Rankine.

The value of $T_{\mathrm{b;\,atmos}}$, and therefore T', must be adjusted until p^* equals the pressure conditions of the subatmospheric distillation being converted. The normalized (to $K_W = 12$) temperature is then converted back to the real K_W basis using Equation (59):

$$DT = T_{\mathrm{b;\,atmos}} - T_{\mathrm{b;\,non\text{-}atmos}} = A(K_W - 12) \times \left(\frac{\log p^*}{760\,\mathrm{mmHg}}\right) \quad (59)$$

For $T_{\mathrm{b;atmos}} > 400\,^\circ\mathrm{F}$, $A = 2.5$.
For $T_{\mathrm{b;atmos}} < 200\,^\circ\mathrm{F}$, $A = 0.0$.
For $200\,^\circ\mathrm{F} < T_{\mathrm{b;atmos}} < 400\,^\circ\mathrm{F}$, $A = 2.5(T_{\mathrm{b;\,atmos}} - 200)/200$

The API has recently proposed a revised correction factor that is similar in form and shown in Equation (60):

$$DT = T_{\mathrm{b;atmos}} - T_{\mathrm{b;non-atmos}} = B(K_W - 15) \times \left(\frac{\log p^*}{760\,\mathrm{mmHg}}\right) \quad (60)$$

For $200\,^\circ\mathrm{F} < T_{\mathrm{b;atmos}} < 600\,^\circ\mathrm{F}$, $B = 3.85$.
For $T_{\mathrm{b;atmos}} < 200\,^\circ\mathrm{F}$, $B = 0.0$.
For $T_{\mathrm{b;atmos}} > 800\,^\circ\mathrm{F}$, $B = 14.9$.
For $600\,^\circ\mathrm{F} < T_{\mathrm{b;atmos}} < 800\,^\circ\mathrm{F}$, $B = 3.85 + 11.02(T_{\mathrm{b;\,atmos}} - 600)/200$.

This latter method using Equation (60) was developed specifically for full-range crude oils. The data from which it was taken were a series of specially assayed common crudes for sale on the world market. For narrower fractions, the Maxwell–Bonnell methods based on Equation (59) are preferable. The user may prefer his/her own plant data to recalibrate the coefficients used.

2.11.2.6 Correcting American Society for Testing and Materials D-86 for Cracking[13,14,75] The following procedure is the classical correction made to ASTM D-86 values in the high-temperature range [>246 °C (475 °F)] to adjust for the cracking of heavier molecules and thus a higher light ends yields than existed in the original sample. The value of this correction procedure has been hotly debated in the last 10 years. An equal number of refining companies can be found on both sides of the controversy – that cracking correction is useless or that it is indispensable. Both sides will claim that proprietary data in their possession prove their respective contentions. For the sake of completeness, it will be included here.

The procedure corresponds to Figure 2.B.1.1 of the API 1964 Technical Data Book[13] (Equation 61). It was

officially removed from the 1987 version 4.[10]

$$\log[\text{D-86_diff}] = -1.587 + 0.00473T_{\text{D-86}} \quad (61)$$

where D-86_diff is the correction that should be made to any D-86 distillation value that exceeds 246 °C (475 °F) and $T_{\text{D-86}}$ is the D-86 value (°F) of concern.

2.11.2.7 Distillation Pressure Interconversion – Gas Chromatography Methods The use of GC equipment is becoming a standard practice for laboratory and on-line analyses of hydrocarbon streams. What must be remembered is that the gas chromatograph will detect the size of the last and presumably largest molecules that elute through the chromatographic column.

The distillation procedures are based on manual observations by an analyst or an automated observation function that mimics an analyst. For this reason, determining the "final boiling point" is a tedious and inaccurate process. It is really difficult to determine the very bottoms of a cut; in fact, it is usually impossible. Absolute purity of the overhead is another issue. GC provides good separation but distillation often does not.

The GC end-point value is artificially skewed to the high end as opposed to what would be observed in a physical distillation. Therefore, the following protocol is proposed (Equation 62):

$$\text{D-2887}_{\text{FBP}} = \text{D-2887}_{98.5\%} \quad (62)$$

Equation (62) is based on the author's experiences with GC analyses and conversions. Using even interpolated values of the 98.5% recovery for the final boiling point is better than using the reported D-2887 end point.

2.11.2.8 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887/D-3710) to American Society for Testing and Materials D-86 Distillation – Method 1 Equation (63) is used to convert what is known as a simulated distillation (SD) in weight-percent to an ASTM D-86 distillation in volume-percent. It is based on API Technical Data Book (1987) procedure 3A3.2.[10] This method provides a one-to-one point correspondence from one distillation type to the other. If one has a full set of distillation data, the next procedure (section 2.12.2.9) may be a preferred method.

$$\text{D-86}(\,) = a(\text{SD})^b F^C \quad (63)$$

where D-86( ) = observed ASTM D-86 temperatures at 0, 10, 30, 50, 70, 90 and 100 vol.-% points, in degrees Rankine, SD( ) = D-2887 temperatures at corresponding weight percentage points, in degrees Rankine. F = a variable parameter given by Equation (64):

$$F = 0.009524(\text{SD}_{10\%})^{0.05437}(\text{SD}_{50\%})^{0.6147} \quad (64)$$

$\text{SD}_{10\%}$ is the simulated distillation temperature at the 10% point, in degrees Rankine, $\text{SD}_{50\%}$ is the simulated distillation temperature at the 50% point, in degrees Rankine, and a, b and c = constants varying with the percentage of liquid sample distilled as given in Table 11.

A standard for SDs, or simdists as they are commonly referred to, is presented in ASTM D-2887 for full-range 0–1000 + °F NBP cuts and in D-3710 which is a procedure for naphtha-based cuts at or below 260 °C (500 °F) NBP. Unfortunately, it is not simple to follow either standard completely to the letter and simdist values may have slightly more variation in their repeatability than is desirable. Use them with care.

2.11.2.9 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887) to American Society for Testing and Materials D-86 Distillation – Method 2 The methodology here is based on API Technical Data Book (1994) Procedure 3A3.1.[9]

This method should be used only for a fully defined assay of a stream. Trying to derive a full TBP curve from three or more such point applications of this method can create problems.

Equations (65–66) are used to interconvert ASTM D-86 and ATM TBP distillation data:

$$\text{D-86}_{50\%} = a(\text{D-2887}_{50\%})^b \quad (65)$$

$$\text{D-86}_{50\%} = \left(\frac{\text{TBP}}{a}\right)^{1/b} \quad (66)$$

where $a = 0.7760$ and $b = 1.040$ for the interconversion of the 50% points, D-2887( ) = vector of simdist boiling point temperatures at 0, 10, 30, 50, 70, 90 and 95 vol.-% distilled, in degrees Fahrenheit, and D-86( ) = vector of observed ASTM D-86 temperatures at corresponding volume percentage distilled, in degrees Fahrenheit.

The procedure works by calculation of differential temperatures from the mid-volume boiling point value and translating that value to the other corresponding member of the pairing.

The difference between adjacent cut points can be determined from a series of equations for each interval

Table 11 GC simulated distillation (SD) (ASTM D-2887) conversion to ASTM D-86 parameters (per Equations 63 and 64)

% Distilled	a	b	c
0	6.0154	0.7445	0.2879
10	4.2262	0.7944	0.2671
30	4.8882	0.7719	0.3450
50	24.1357	0.5425	0.7132
70	1.0835	0.9867	0.0486
90	1.0956	0.9834	0.0354
100	1.9073	0.9007	0.0625

(Equation 67):

$$\text{D-86_diff (I)} = C_0(\text{D-2887_diff})^{C_1} \quad (67)$$

where C_0 and C_1 are coefficients for varying temperature ranges, D-86_diff( ) and D-2887_diff( ). Their vectors are shown in Table 12. Temperature values and differences are in Rankine or Fahrenheit degrees.

2.11.2.10 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887) to American Society for Testing and Materials D-86 Distillation – Method 3[158,159] The methodology here is based on data published by Hewlett-Packard Analyzer Division. It provides a point-to-point translation of data from one assay to the other (Equation 68):

$$\text{D-86}(\ ) = f[\text{D-2887}(\ )] \quad (68)$$

where D-2887( ) = vector of simdist boiling point temperatures at 0, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 95 and 100 vol.-% distilled, in degrees Fahrenheit, and D-86( ) = vector of observed ASTM D-86 temperatures at the corresponding volume percentage distilled, in degrees Fahrenheit.

To determine estimated ASTM D-2887 values from measured D-86 values, reverse the procedure. In actual practice this would require several iterative calculations, no reverse transform function being readily available. It is, in reality, easier and more reliable simply to take GC data if the information is needed on any sort of regular basis.

The equations for simdist( ) to D-86( ) are Equations (69–77):

$$\text{D-86}_{\text{IP}} = 46.57 + 0.5829\text{D-2887}_{10\%} + 0.3480\text{D-2887}_{\text{IP}} \quad (69)$$

$$\text{D-86}_{10\%} = 33.31 + 0.6156\text{D-2887}_{10\%} + 0.3511\text{D-2887}_{20\%} \quad (70)$$

$$\text{D-86}_{20\%} = 22.41 + 0.4890\text{D-2887}_{30\%} + 0.2753\text{D-2887}_{20\%} + 0.2171\text{D-2887}_{10\%} \quad (71)$$

$$\text{D-86}_{30\%} = 14.43 + 0.4704\text{D-2887}_{30\%} + 0.2837\text{D-2887}_{20\%} + 0.2278\text{D-2887}_{50\%} \quad (72)$$

Table 12 Coefficients for D-86–D-2887 conversion (according to Equations 65–67)

Index value	Cut point range (%)	C_0	C_1
1	100–90	2.603	0.6956
2	90–70	0.3079	1.234
3	70–50	0.1486	1.429
4	50–30	0.0798	1.539
5	30–10	0.06069	1.518
6	10–0	0.3047	1.126

$$\text{D-86}_{50\%} = 4.876 + 0.960\text{D-2887}_{50\%} \quad (73)$$

$$\text{D-86}_{70\%} = 0.911 + 0.5198\text{D-2887}_{80\%} + 0.3326\text{D-2887}_{70\%} + 0.1016\text{D-2887}_{30\%} \quad (74)$$

$$\text{D-86}_{80\%} = 0.279 + 0.7594\text{D-2887}_{80\%} + 0.2833\text{D-2887}_{95\%} - 0.0998\text{D-2887}_{100\%} \quad (75)$$

$$\text{D-86}_{95\%} = -1.973 + 0.6146\text{D-2887}_{90\%} + 0.3191\text{D-2887}_{95\%} \quad (76)$$

$$\text{D-86}_{100\%} = 34.18 + 1.1486\text{D-2887}_{95\%} - 0.5921 \times \text{D-2887}_{90\%} + 0.3154\text{D-2887}_{100\%} \quad (77)$$

To determine calculated ASTM D-2887 values from measured D-86 values, reverse the procedure. The units for the above equations are all degrees Fahrenheit.

2.11.2.11 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887) to True Boiling Point Distillation at 760 mmHg[9] The methodology here is based on API Technical Data Book (1994) Procedure 3A3.3.

Equations (78) and (79) are used to interconvert ASTM D-2887 and ATM TBP distillation data:

$$\text{TBP}_{50\%} = a(\text{D-2887}_{50\%})^b \quad (78)$$

$$\text{D-2887}_{50\%} = \left(\frac{\text{TBP}}{a}\right)^{1/b} \quad (79)$$

where $a = 0.8718$ and $b = 1.026$ for the interconversion of the 50% points, TBP temperatures at 0, 10, 30, 50, 70, 90 and 95 vol.-% distilled, in degrees Rankine, and D-2887 = observed ASTM D-2887 temperatures at corresponding volume percentage distilled, in degrees Rankine.

The procedure works by calculating differential temperatures from the mid-volume boiling point value and translating that value to the other corresponding member of the pairing.

The difference between adjacent cut points can be determined from a series of equations for each interval (Equation 80):

$$\text{TBP_diff (I)} = C_0(\text{D-2887_diff})^{C_1} \quad (80)$$

where C_0 and C_1 are coefficients for varying temperature ranges, TBP_diff( ) and D-2887_diff( ). Their vectors are shown in Table 13. Temperature values and differences are in degrees Rankine or Fahrenheit.

To determine the TBP values at any percentage distilled, add or subtract the proper differentials from the predicted 50% TBP temperature (Equations 81–86):

$$\text{TBP}_{0\%} = \text{TBP}_{50\%} - \text{TBP_diff(4)} - \text{TBP_diff(5)} - \text{TBP_diff(6)} \quad (81)$$

Table 13 Coefficients for D-2887–TBP conversion (according to Equations 78–80)

Index value	Cut point range (%)	C_0	C_1
1	95–90	0.9748	0.8723
2	90–70	0.3153	1.294
3	70–50	0.1986	1.398
4	50–30	0.0543	1.699
5	30–10	0.0119	2.025
6	10–5	0.1578	1.430

$$\text{TBP}_{10\%} = \text{TBP}_{50\%} - \text{TBP_diff}(4) - \text{TBP_diff}(5) \quad (82)$$

$$\text{TBP}_{30\%} = \text{TBP}_{50\%} - \text{TBP_diff}(4) \quad (83)$$

$$\text{TBP}_{70\%} = \text{TBP}_{50\%} + \text{TBP_diff}(3) \quad (84)$$

$$\text{TBP}_{90\%} = \text{TBP}_{50\%} + \text{TBP_diff}(3) + \text{TBP_diff}(2) \quad (85)$$

$$\text{TBP}_{100\%} = \text{TBP}_{50\%} + \text{TBP_diff}(3) - \text{TBP_diff}(2) + \text{TBP_diff}(1) \quad (86)$$

To determine calculated ASTM D-2887 values from measured TBP values, reverse the procedure. The units for the above equations are all degrees Fahrenheit.

2.11.2.12 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887) to American Society for Testing and Materials D-1160 Distillation – Method 3[158] The methodology provides a point-to-point translation of data from one assay to the other (Equation 87):

$$\text{D-1160}(\ ) = f[\text{D-2887}(\ )] \quad (87)$$

where D-2887( ) = vector of simdist boiling point temperatures at 0, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 95 and 100 vol.-% distilled, in degrees Fahrenheit, and D-1160( ) = vector of observed ASTM D-1160 temperatures at the corresponding volume percentage distilled, in degrees Fahrenheit.

To determine estimated ASTM D-2887 values from measured D-1160 values, reverse the procedure. Unfortunately, this would require several iterative calculations, no reverse transform function being readily available. It is, in reality, easier and more reliable simply to take actual GC data if the information is needed on any sort of regular basis.

The equations for simdist( ) to D-1160( ) are Equations (88–99):

$$\text{D-1160}_{\text{IP}} = 574.7 + 0.3851\text{D-2887}_{10\%} + 0.3660\text{D-2887}_{\text{IP}} - 0.5902\text{D-2887}_{90\%} \quad (88)$$

$$\text{D-1160}_{5\%} = 86.90 - 0.3826\text{D-2887}_{5\%} + 1.931\text{D-2887}_{10\%} - 0.6244\text{D-2887}_{30\%} \quad (89)$$

$$\text{D-1160}_{10\%} = 12.64 + 1.865\text{D-2887}_{10\%} + 0.1127\text{D-2887}_{\text{IP}} - 0.9729\text{D-2887}_{5\%} \quad (90)$$

$$\text{D-1160}_{20\%} = 32.45 + 1.199\text{D-2887}_{20\%} - 0.2398\text{D-2887}_{5\%} \quad (91)$$

$$\text{D-1160}_{30\%} = 10.39 + 1.282\text{D-2887}_{30\%} - 0.3070\text{D-2887}_{10\%} \quad (92)$$

$$\text{D-1160}_{40\%} = 7.249 + 1.117\text{D-2887}_{40\%} - 0.1464\text{D-2887}_{5\%} \quad (93)$$

$$\text{D-1160}_{50\%} = -7.867 + 1.151\text{D-2887}_{50\%} - 0.1702\text{D-2887}_{10\%} \quad (94)$$

$$\text{D-1160}_{60\%} = -20.78 + 2.172\text{D-2887}_{60\%} - 1.187\text{D-2887}_{50\%} \quad (95)$$

$$\text{D-1160}_{70\%} = -28.28 + 0.0398\text{D-2887}_{70\%} + 0.9497\text{D-2887}_{80\%} \quad (96)$$

$$\text{D-1160}_{80\%} = -56.82 + 1.302\text{D-2887}_{80\%} - 0.2840\text{D-2887}_{50\%} \quad (97)$$

$$\text{D-1160}_{90\%} = -54.74 + 1.040\text{D-2887}_{90\%} \quad (98)$$

$$\text{D-1160}_{95\%} = 56.08 + 1.428\text{D-2887}_{95\%} - 0.2514 \times \text{D-2887}_{50\%} + 0.2724\text{D-2887}_{100\%} \quad (99)$$

To determine calculated ASTM D-2887 values from measured D-1160 values, reverse the procedure. The units for the above equations are all degrees Fahrenheit.

3 PREDICTION OF STREAM/STOCK PROPERTIES FROM INSPECTION PROPERTY DATA

3.1 Property Predictions in General[83,89,134,135,143]

The prediction of physical properties is an absolute necessity for any sort of intelligent process and control engineering. It is also a vital tool in the analysis and synthesis of all industrially important organic compounds. As these statements are true of individual volumes of pure components, so too do they apply to mixtures of these components.

Most methods for estimating the properties of hydrocarbon cut fractions were initially derived from relationships that can be ascertained by examining pure components. Boiling point/MW/gravity is an obvious set of positive monotonic correlations where model matches data for nearly all compounds. Refractive index (RI) and

MW for a specific type of compound (aromatics, paraffins, etc.) is another time-tested functional pairing.

Figures 17, 18(a–c), and 19(a) illustrate the variation of various hydrocarbon pure compound physical properties as a function of carbon number and type.

Figure 16 Composition–index relationships: comparison of characterization parameters.

Figure 17 *n*-Alkanes: relationship of melting point and chain length. Similar paraffin analogs exist for other physical properties.

Several of these pure component mathematical models have been modified and extended into the realm of hydrocarbon ''pseudo''-components, a lumping procedure whereby a narrow cut stream is described in terms of one or just a few discrete compounds whose properties are estimated by some of the equations found in this work. MW correlates with gravity and MEABP. Pseudocritical temperature is a strong function of gravity and

Figure 18 (a) NBP, (b) SG and (c) absolute viscosity versus carbon number for aromatics.

Figure 19 (a) APs of some hydrocarbon families as a function of MW and (b) AP as a function of Watson *K* and average boiling point.

MABP. Any of these properties (MW, gravity, NBP) may be well approximated from a knowledge of any other two of the set.

An historic paper by Watson et al.[152] is a nomograph to predict the AP from K_W, the Watson *K* factor, which Figure 19 summarizes graphically, clearly showing the relationship of AP to MW and molecular type.

In other cases, properties of an entire fraction may be estimated from one or two inspection properties taken for the cut as a whole – without any ''hypothetical'' component lumping being assumed.

None of the methods can be expected to perform perfectly. There is always an error factor involved in the use of any of them. The error derives from two primary sources. The first is in the measurement (bias, average absolute deviations, etc.) of the data upon which the correlation is based. The second is the error of fit for the mathematical derivations from the data. Other error sources include mistranscription from old sources, linear scaling of exponentiation or other transcendental mathematical functions, round off/truncation errors for multiple loop computer processing, change of parameter dimensional units or computational accuracy limitations on significant digits.

Classical statistical analysis tells us that the variance of the correlation is the weighted sum of the variances of the functions and data used to generate the correlation. If all but one of the variances are small, the one that is large will be the determining factor in the overall validity of the fit. Thus, new correlations of any sort are limited by the quality of available data and the amount of work necessary to reduce inaccuracies at all levels of the analysis. Use of established or ''tried and true'' models is often the preferred means of such estimation.

In the following pages, several legacy prediction methods are presented in addition to some more recently examined and published correlations. Use any of them with care. If they yield results that are unexpected, trust one's instincts and review the data and math manipulations for suitability. Two separate correlations that predict a single property give results that may vary significantly from one another, in spite of being derived from the same data. In another laboratory facility down the street, quite the opposite may be true. There is enough variation in data, fit and suitability of these methods that one should always ''calibrate'' real data to the assumed estimation method and use whichever procedure best fits the localized truth the best. For this reason, several similar correlations are presented, based on the gross error of fit for hydrocarbon streams in general. Just because the API Technical Data Committee, for example, fits MW one way does not mean that your data will be so well

served. The reader should possibly try an alternative method presented here or develop one independently if data calibrations fail to show reasonable accuracy and applicability.

3.2 Property Predictions Derived Directly from Observed Data or Other Derived Properties

The following properties can be estimated or predicted directly from simple inspection property measurements. The predicted properties, themselves, can usually (Watson K is an exception) be readily obtained by one or more standard analysis techniques. It may not always be feasible or timely to do so, so these empirical alternatives are presented here. They have been correlated against a significant amount of real historical data.

The correlations presented here either predict derived properties directly from simple inspection property measurements or they use such derived data in hybrid correlations.

3.2.1 Aniline Point

For pure components, several resources[59,63,80,92,96,109] provide tables on the APs of various pure hydrocarbons. This is illustrated by Figure 19(a). Within any hydrocarbon family, the AP increases with MW. Aromatics tend to have the lowest and paraffins the highest values of AP. It is a straightforward exercise to construct a predictive method for the APs for pure compounds, based on MW and compound type.

Several nomographs exist which can be used to estimate APs for petroleum fractions. The Winn nomograph is a traditional part of the API Technical Data Book[10] as Figure 2B6.1. The original Watson nomograph is shown here in Figure 19(b).

The recommended procedure for predicting the CN index of petroleum fractions with lots of information is a recently developed (reregressed) version of the ASTM D-4737-87 procedure. This correlation most accurately predicts the data but requires the liquid density and distillation temperatures at three different specific points.

Other classical AP prediction procedures based on disparate property data are also presented here.

3.2.1.1 Aniline Point from American Petroleum Institute Gravity and Distillation Data – Method 1 The AP can be estimated from known stream gravity and boiling point by this method (Equation 100):

$$\mathrm{AP} = 0.317(\text{D-86}_{50\%}) + 0.40(\text{D-86}_{50\%})(\mathrm{API}) - 298 \tag{100}$$

where $\text{D-86}_{50\%}$ is the cut mid-boiling temperature (degrees Rankine) and API is the API gravity of the cut.

3.2.1.2 Aniline Point from American Petroleum Institute Gravity and Distillation Data – Method 2 An alternative equation to (89) is Equation (101):

$$\begin{aligned}\mathrm{AP}(^\circ\mathrm{F}) = {} & -151.0 + 0.254\mathrm{MEABP} \\ & - 2.87(\mathrm{MEABP})^{0.6667}\mathrm{SG} \\ & + \frac{34.6(\mathrm{MEABP})^{0.3334}}{\mathrm{SG}}\end{aligned} \tag{101}$$

where AP and MEABP are in degrees Rankine.

Equation (101) is more accurate than Equation (100) but it is more complex and requires derived knowledge of the MEABP. It can be estimated as a mid-volume (50%) point or VABP, but the resulting accuracy of the equation will be no better than the previous correlation.

3.2.1.3 Aniline Point from Gravity and Watson K[156] – Method 1 Another derivation of boiling point and gravity is the Watson K characterization factor. It correlates extremely well with AP (Equation 102):

$$\mathrm{AP}(^\circ\mathrm{F}) = \frac{K_\mathrm{W} - 8.3 - 0.0032(\mathrm{API})}{0.0153} \tag{102}$$

where API is the measured or assumed API gravity.

Equation (102) is known as the Woodle method (current API method 2B6.1) and is the API's recommended method, given a lack of complete quality data. One algebraic rearrangement of this correlation is Equation (103):

$$\mathrm{AP}(^\circ\mathrm{F}) = \frac{65.36[\mathrm{MEABP}]^{1/3}}{\mathrm{SG}} - 267.5 - \frac{296.0}{\mathrm{SG}} \tag{103}$$

Another derivative expression of this correlation is Equation (104):

$$\mathrm{AP}(^\circ\mathrm{F}) = -1254 - 0.139\mathrm{MEABP} + 107.8K_\mathrm{W} + 868.7\mathrm{SG} \tag{104}$$

For a narrow range cut, one could conceivably substitute the TBP 50% point or the VABP into the equation. Studies of this idea showed an average error of approximately 8% by doing this. Equation (93) is now API TDB procedure 2B9.1.

The estimated accuracies of AP correlations are given in Table 14.

3.2.1.4 Aniline Point from Gravity and Cetane Index – Method 1 Equation (105) is used:

$$\begin{aligned}\mathrm{AP}(^\circ\mathrm{F}) = {} & 67\,220 + 7.39(\mathrm{API}) - 1.714(\mathrm{CI}) + 2255 \\ & \times \left(\frac{\ln(\mathrm{CI})}{\mathrm{API}}\right)^{0.01} - 70\,600 \left(\frac{\ln((\mathrm{API})^2/\mathrm{CI})}{\mathrm{API}}\right)^{0.01}\end{aligned} \tag{105}$$

where API is the measured or assumed API gravity.

Table 14 Estimated accuracy of AP correlation (AP range 26–250 °F)

Method	Average error (%)	Average bias (%)
Equation (100)	2.87	0.50
Equation (101)	3.88	0.24
Equations (102–104)	3.53	−0.42

Method 2. Equation (106) was formulated as a simple derivation of Equation (105):

$$\mathrm{AP}(^\circ\mathrm{F}) = 60.39 - 0.82(\mathrm{API}) + 2.36(\mathrm{CI}) \quad (106)$$

This procedure, although very simple, is slightly less accurate than using Equation (105). It is reported here, however, as it makes a differential equation relating AP to gravity or CI very simple to evaluate for control or planning optimization systems.

An analysis of the errors for the procedure is given in Table 15.

Both methods tend to predict values higher than experiments. The errors of this method increase greatly when predicted rather than measured CI values are used.

3.2.1.5 Aniline Point from Gravity and Flash Point This method relates the AP to the FP of petroleum fractions. This correlation differs from the previous one because it uses the experimental CI to predict the AP of the fraction from Equation (107):

$$\mathrm{AP}(^\circ\mathrm{F}) = 84 + 0.994(\mathrm{API}) + 0.18\mathrm{FP} - \frac{10\mathrm{API}^2}{\mathrm{FP}^{1.5}} \quad (107)$$

where FP is the flash point (°F) and API is the measured or assumed API gravity.

3.2.1.6 Aniline Point from Smoke Point Equation (108) is used:

$$\mathrm{AP}(^\circ\mathrm{F}) = 12\,140\left\{\frac{\mathrm{SP} + 3500 + 3021\ln(\mathrm{SG})}{3522(\mathrm{SG}) - 1}\right\} \quad (108)$$

where SP is in (mm height).

The validation statistics for these methods are given in Table 16. Equation (97) is now API procedure 2B14.1.

Table 15 Estimated accuracy of AP correlations (AP range 123–184 °F, CI range 31–73 °F)

Method	Average error (%)	Average bias (%)
Equation (105)	2.02	0.08
Equation (106)	3.02	0.35

Table 16 Error analysis for revised prediction methods (FP range 95.0–460.0 °F, AP range 11.0–184.5 °F, SG range 0.76–0.86, SP range 15–42 mm)

	Equation (107)	Equation (108)
Average absolute error (mm)	3.22	1.7
Average error (%)	2.11	7.3
Average bias error (%)	0.18	0.04

3.2.2 Cetane Index[52,53,147]

3.2.2.1 Cetane Index from American Petroleum Institute Gravity and Distillation Data – Method 1 CI can be estimated from known stream gravity and boiling point by one of two methods found in ASTM D-976 (1991–1995 versions) and ASTM D-613 (Equation 109) (temperatures in degrees Fahrenheit).

$$\begin{aligned}\mathrm{CI} = {} & C_7(\text{D-86}_{50\%})^2 + C_6(\text{D-86}_{50\%}) + C_5(\log \mathrm{MBP})^2 \\ & + C_4(\mathrm{API})(\log \mathrm{MBP}) + C_3(\mathrm{API})^2 \\ & + C_2(\log \mathrm{MBP}) + C_1(\mathrm{API}) + C_0 \end{aligned} \quad (109)$$

where log MBP = the logarithm of D-86 mid-boiling point, i.e. (Equations 110 and 111)

$$\mathrm{MBP} = \log(\text{D-86}_{50\%}) \quad (110)$$

$$\mathrm{MBP} = \text{D-976 revised-mean average BP} \quad (111)$$

and C_0–C_7 are coefficients defined in Table 17. The 1995 version is the current API method 2B12.1.

3.2.2.2 Cetane Index from American Petroleum Institute Gravity and Distillation Data – Method 2 A simpler correlation that requires only the liquid density and MEABP is suitable for use. This correlation is a revision of the ASTM D-976-91 procedure. This procedure (the current API method 2B12.1) is represented by Equation (112):

Table 17 CI correlation parameters (Equation 109)

CI parameter	ASTM method		
	D-976 (1991)	(D-976 1995)	D-613
C_0	−420.34	−81.7	419.6
C_1	0.0	0.0	−4.781
C_2	0.0	0.0	−423.5
C_3	0.016	−0.0165	0.01247
C_4	0.192	0.893	2.209
C_5	65.01	8.12	97.83
C_6	0.0	0.0	0.0
C_7	−0.0001809	−0.000032	0.0

$$\mathrm{CI} = 415.26 - 7.673\mathrm{API} + 3.505\mathrm{API}\log(\mathrm{MEABP}) + 0.186\mathrm{MEABP} - 193.8\log(\mathrm{MEABP}) \quad (112)$$

where MEABP is in (°F).

An analysis of the errors for both methods is given in Table 18.

3.2.2.3 Cetane Index from American Petroleum Institute Gravity and Distillation Data – Method 3 A final alternative form of the D-976 method is Equation (113):

$$\mathrm{CI} = 454.7 - 1641S + 774.74S^2 - 0.554(\mathrm{D\text{-}86_{50\%}}) + 97.803(\log \mathrm{D\text{-}86_{50\%}})^2 \quad (113)$$

where S = density (g cm^{-3}) at 15 °C and D-86$_{50\%}$ = distillation temperature (°C) of 50% distillate recovery.

These equations are limited to petroleum liquids with a 90% boiling temperature <343 °C (650 °F). ASTM method D-613 tends to overpredict and is only a slight improvement over ASTM D-976-80. The error of Equation (113) is about the same as that for Equation (112).

3.2.2.4 Cetane Index from Gravity and Assay Data via Expanded Distillation Curve Usage – Alternate Methods CI is also calculated using the methods of ASTM D-4737 (Equation 114):

$$\mathrm{CI} = 45.2 + 0.0892\mathrm{TBP}_{10} + (0.131 + 0.901\mathrm{B})\mathrm{TBP}_{50} + (0.0523 - 0.4208)\mathrm{TBP}_{90} + 0.00049 \times (\mathrm{TBP}_{10}^2 - \mathrm{TBP}_{90}^2) + 107S + 60S^2 \quad (114)$$

where CI = calculated cetane index, SG = specific gravity at 15 °C (60 °F) (g cm^{-3}) and TBP$_{10,50,90\%}$ are true boiling points (°F).

An alternate formulation of Equation (103) using D86 values is Equation (115):

$$\mathrm{CI} = C_0 + C_1A + C_2B + C_3C + C_4BD + C_5CD + C_6A^2 + C_7C^2 + C_8D + C_9D^2 \quad (115)$$

where A = D-86$_{10\%}$ − 488(°F) or D-86$_{10\%}$ − 215(K), B = D-86$_{50\%}$ − 533(°F) or D-86$_{50\%}$ − 260(K), C = D-86$_{90\%}$ − 583(°F) or D-86$_{90\%}$ − 310(K), $D = \exp[-3.5(\mathrm{SG} - 0.85)] - 1$, SG is the specific gravity at 15 °C (g cm^{-3}), D-86$_{10\%}$ = 10% volume boiling temperature (R or K), D-86$_{50\%}$ = mid-boiling temperature (R or K) and D-86$_{90\%}$ = 90% volume boiling temperature (R or K).

Table 18 Estimated accuracy of CI correlation (API range 27–47, MEABP range 360–700 °F)

Method	Average error (%)	Average bias error (%)
Equation (109)	0.6	<0.1
Equation (112)	2.9	<0.2

CI correlation parameters per Equation (115) are given in Table 19 and correspond to API procedure 2B12.2.

The error analysis of CI by Equations (114) and (115) is as follows: CI range 31–73.0, average absolute error 4.31 °F, average error 4.22% and average bias error 0.23%.

3.2.2.5 Cetane Index from Aniline Point Data[110] The method represented by Equation (116) is from Alberta Research Corporation's work. It is fairly good correlation for hydrotreated and hydrocracked heavy naphtha and diesel stocks.

$$\mathrm{CI} = 0.0007685(\mathrm{AP})^2 + 0.471(\mathrm{AP}) + 13.07 \quad (116)$$

where AP is in degrees Fahrenheit.

The reported error analysis of CI by Equation (116) is as follows: AP range 78–166.5 °F, average error 6.43% and average bias error −0.2%.

3.2.2.6 Cetane Index from Aniline Point, Density and Viscosity Data[110]

Canadian General Standards Board Correlation. The Canadian General Standards Board (CGSB) estimates CI via Equation (117):

$$\mathrm{CI} = 77.76 + 0.1765(1.0 + \mathrm{AP}) + 0.003867(\mathrm{AP})^2 - 11.62X + 0.584X^2 - 0.6350V_{40c} \quad (117)$$

where AP is in degrees Celsius, X is given by Equation (118):

$$X = \frac{T_{10} + T_{50} + T_{90} + 820.0}{200D^2} \quad (118)$$

(g cm^{-1}) T_{10}, T_{50}, T_{90} = 10, 50 and 90% D-86 distillation temperatures, (°C), D = density (g cm^{-1}) at 15 °C (kg L^{-1}) and V_{40c} = viscosity at 40 °C (cSt).

Table 19 CI correlation parameters per Equation (115)

CI parameter	ASTM method D-4737-96
C_0	47.7
C_1	−0.0094
C_2	+0.269
C_3	−0.009
C_4	0.317
C_5	−0.2
C_6	0.00004
C_7	−0.000279
C_8	97.9
C_9	1.3

The estimated error analysis of CI by Equation (117) is as follows: AP range 83.8–166.5 °F, average error 7.46% and average bias error −1.7%.

Modified Calculated Carbon Aromaticity Index Method. Equation (119) is used:

$$\mathrm{CI} = -0.3656(\mathrm{CCAI}) + 345.1 \tag{119}$$

where CCAI is given by Equation (120):

$$\mathrm{CCAI} = D - 81 - 141\log[\log(V + 0.85)] \tag{120}$$

D = density ($\mathrm{g\,cm^{-1}}$) at 15 °C ($\mathrm{mg\,L^{-1}}$) and V = kinematic viscosity at 50 °C (cSt). This equation is probably the most promising as a predictor of CI without regard to the source of the diesel stock.

Observed errors of CI by Equation (119) are as follows: AP range 78–166.5 °F, average error 5.61% and average bias error −1.5%.

3.2.3 Carbon Numbers/Index[102,112,117,136,140,146]

A significant portion of any crude stock carbon remains with the heavier residues upon separation, with as little as 0.01 wt-% of the total crude carbon being removed with the gas-oils.

A quick and convenient method was developed for the prediction of the Conradson carbon number (CC) of petroleum fractions. The corresponding data for this correlation were divided into two sections: lower MW gas-oils and higher MW crude oils and residues.

Several equations for carbon number prediction have been reported, as follows:

3.2.3.1 Conradson Carbon Number from American Petroleum Institute Gravity – Method 1 This uses Equation (121):

$$\mathrm{CC\ (wt\text{-}\%)} = -0.2875 + 52\,715(\mathrm{API})^{-3.75} \tag{121}$$

where API = (141.5/SG) − 131.5. This is the better correlation for gas-oils, where CC are in the range 0.01–5.5 wt-% with API gravities between 11 and 40.

3.2.3.2 Conradson Carbon Number from American Petroleum Institute Gravity – Method 2 For full range crudes and crude/vacuum resid fractions, Equation (122) may be a better choice:

$$\mathrm{CC(wt\text{-}\%)} = -33.63 + 85.08(\mathrm{API})^{-0.25} \tag{122}$$

3.2.3.3 Conradson Carbon Number from Watson K and Distillation Data This prediction method (Equation 123), when used for stocks with API < 25, predicts higher CC values for heavy crudes and resids very well. Stocks with lower CC numbers must be used carefully.

$$\mathrm{CC(wt\text{-}\%)} = -507.7 + 2.66\mathrm{API} + 0.024\mathrm{MEABP} + 129.4 \times \ln(\mathrm{MEABP})88.29(\mathrm{API})^{-0.15} - 48.63K_{\mathrm{W}} \tag{123}$$

A summary of the error analysis for the above three methods is given in Table 20.

3.2.3.4 Bureau of Mines Correlation Index from American Petroleum Institute Gravity and Distillation Data This is an alternative method for calculating the CCs of crude oils and residues (Equation 124):

$$\mathrm{BMCI} = \frac{48\,640}{\text{D-86}_{50\%}} + 473.7\mathrm{SG} - 456.8 \tag{124}$$

where D-$86_{50\%}$ is the mid-boiling temperature (kelvin).

3.2.3.5 Interconversion of Ramsbottom Carbon Number (American Society for Testing and Materials D-529) and Conradson Carbon Number (American Society for Testing and Materials D-189) Figure 20 shows the relationship between these two quantities. They are not identical at all. The graph can be represented by Equation (125):

$$\log \mathrm{RC} = a + b[\log(\mathrm{CC})] + c[\log(\mathrm{CC})]^2 \tag{125}$$

where RC is the Ramsbottom carbon (wt-%) and CC is the Conradson carbon (wt-%).

3.2.4 Flash Point

The FP can be estimated from known stream boiling point data by four commonly used and similar methods. On average, the open-cup tests predict a FP 11–17 °C (20–30 °F) higher than that of the closed-cup (Pensky-Martin) estimations. In general, the closed-cup method is used most frequently for light-end fuel oils, whereas the open-cup method is used for the heavier residuum-like fractions.

3.2.4.1 Flash Point from Distillation Data Preferred methods for open-cup FP value predictions are represented by Equations (126–128):

$$\mathrm{FP\ (^{\circ}F)} = 0.64(\text{D-86}_{10\%}) - 100 \tag{126}$$

Table 20 Estimated accuracy of carbon content correlations

Method	Average error (%)	Average bias (%)
Equation (121)	0.17	0.0
Equation (122)	1.19	0.0
Equation (123)	3.02	0.35

Figure 20 Conversion between Conradson carbon residue and Ramsbottom carbon residue.

where $D\text{-}86_{10\%}$ is the 10% (measured/estimated) value.

$$\text{FP } (^\circ\text{F}) = 0.64(\text{D-}86_{10\%} - \text{D-}86_{\text{IP}}) \tag{127}$$

This equation is a form also used fairly often.

$$\text{FP } (^\circ\text{F}) = 0.68(\text{D-}86_{10\%}) - 109.6 \tag{128}$$

where $D\text{-}86_{10\%} = 10\%$ (measured/estimated) value and $D\text{-}86_{\text{IP}}$ = initial point D-86 value. This equation is the preferred API method for open-cup value prediction and is procedure 2B7.1 in the API Technical Data Book.

Equations (127) and (128) are based on an analysis of the API databank, which showed a possible linear relationship between measured FP and the $D\text{-}86_{(10\%)}$ point. The equation's coefficients were developed in a standard regression fashion. Neither has been adopted as a standard as yet, but they are often useful formulations.

Preferred methods for closed-cup value predictions are represented by Equations (129–131):

$$\text{FP } (^\circ\text{F}) = 0.75(\text{TBP}_{5\%} - 100) \tag{129}$$

where $\text{TBP}_{5\%}$ (°F) is the 5% (measured or estimated) cut TBP value. This method is based on the author's experience at modeling hydrocarbon distillation units. It is presented as an alternative.

$$\text{FP } (^\circ\text{R})^{-1} = \frac{-0.01457 + 2.849}{\text{D86}_{10\%}} + 0.001903 \ln(\text{D-}86_{10\%}) \tag{130}$$

where $D\text{-}86_{10\%}$ is the 10% (measured or estimated) value in degrees Rankine (note: absolute form). Equation (130) is known as the Riazi FP and is a widely used correlation in industry.

This is known as the Nelson equation and is a widely used procedure.

$$\text{FP } (^\circ\text{F}) = 0.69(\text{D-}86_{10\%}) - 118.2 \tag{131}$$

where $D\text{-}86_{10\%}$ is the 10% (measured/estimated) value. This method is based on an analysis of the API databank which showed basically a linear relationship between measured FP and the 10% D-86 point. It is the currently preferred API method for closed-cup predictions.

An analysis of the experimental errors of Equations (125) and (130) is shown in Table 21. The use of other equations may yield adequate results, but these should provide the most accurate estimates, short of fitting one's own proprietary data.

3.2.4.2 Flash Point from Aniline Point and Distillation Data Equation (132) is used:

$$\text{FP } (^\circ\text{R}) = 6989 + 6.0(\text{MEABP}) - 7.67(\text{AP}) - 918.4 \ln\left(\frac{\text{MEABP}}{\text{AP}}\right)^{0.8} - 3683 \times \exp\left(\frac{\text{MEABP}}{\text{AP}}\right)^{0.4} \quad (132)$$

where AP and MEABP are in degrees Rankine.

3.2.4.3 Flash Point from Aniline Point and Smoke Point Equation (133) is used:

$$\text{FP } (^\circ\text{F}) = 116\,814 + 191.0(\text{AP}) + 21.0\exp\left(\frac{\text{AP}}{\text{SP}}\right)^{0.8} - 9419[(\text{AP} + \text{SP})]^{0.5} + 186.0(\text{SP}) \quad (133)$$

where AP is in degrees Fahrenheit and SP is in millimeters.

An analysis of the errors for Equations (132) and (133) is given in Table 22.

Table 21 Analysis of recommended procedures for FP

	Equation (126): Nelson (closed cup)	Equation (130): Riazi (open cup)
FP range (°F)	20–460	95–325
D-$86_{10\%}$ range (°F)	347–855	287–630
Average absolute error (°F)	9.04	6.95
Average bias (°F)	−7.06	−5.38

Table 22 FP, AP and SP error analysis

	Equation (132)	Equation (133)
FP range (°F)	95.0–460.0	105.0–227.3
AP range (°F)	123.0–184.5	123.0–153.0
SP range (mm)	n/a	18.0–27.0
Mean boiling range (°F)	297.0–936.0	n/a
Average absolute error (°F)	8.97	7.62
Average error (%)	4.25	5.24
Average bias error (%)	0.28	0.38

3.2.5 Diesel Index

DI is not an easy measurement to make on a consistent and repeatable basis, yet it is a very useful parameter for the prediction of several other derived property estimates.

3.2.5.1 Diesel Index as a Function of Gravity and Aniline Point DI is defined by a calculation based on the aniline gravity constant (AG), which is the product of AP and API gravity (Equations 134 and 135).

$$\text{AG} = (\text{AP})(\text{API gravity}) \quad (134)$$

$$\text{DI} = \frac{\text{AG}}{100} \quad (135)$$

3.2.5.2 Diesel Index as a Function of Watson K and Mid-boiling Point Equation (136) finds DI as a function of Watson K and D-$86_{50\%}$:

$$\text{DI} = (K_\text{W} - 10.45)[-0.03252(\text{D-}86_{50\%} - 400) + 46.83] \quad (136)$$

where D-$86_{50\%}$ = mid-boiling point − D-$86_{50\%}$ point (°F).

3.2.6 Smoke Point Prediction[84]

3.2.6.1 Smoke Point from Aniline Point and Gravity Data Equation (137) is used:

$$\text{SP} = -255.3 + 2.04(\text{AP}) - 240.8\ln(\text{SG}) + 7727\left(\frac{\text{SG}}{\text{AP}}\right) \quad (137)$$

where SP is in mm height and AP is in degrees Fahrenheit. This is known as the Jenkins equation and is also the API's procedure 2B8.1. The average error of the correlation based on API's databank of experimental measurements is 6.7%, with an average bias of +0.5%. API's use of predicted APs to extend the correlational databank will increase the error and bias of the procedure to an average of 8.8% and 4.0%, respectively.

3.2.6.2 Smoke Point from Aniline Point and Distillation Data Equation (138) is used:

$$\text{SP} = 0.556 - 0.149(\text{MEABP}) + 0.52(\text{AP}) + 0.75\left(\frac{\text{MEABP}}{\text{AP}}\right)^2 + 2084\frac{[\exp(\text{MEABP})]^{0.01}}{(\text{AP})^{2.1}} \quad (138)$$

where SP is in mm height, AP and MEABP are in degrees Fahrenheit.

3.2.6.3 Smoke Point from Flash Point and Distillation Data Equation (139) is used:

$$SP = 1686 - 0.325FP + 5.03(API) - 2252 \times \ln\left(\frac{FP}{API}^{-0.3} - 2.982\frac{(API)^{0.2}}{(FP)^{0.5}}\right) \quad (139)$$

where SP is in mm height and FP is in degrees Fahrenheit.

An analysis of the errors for Equations (138) and (139) is given in Table 23.

3.2.6.4 Smoke Point from Gravity and Distillation Data Equation (140) is used:

$$\ln(SP)(mm) = -1.19 + \frac{0.677(MEABP)^{0.3334}}{SG} - 0.00467(MEABP) \quad (140)$$

where SG is at 60 °F and MEABP is in degrees Fahrenheit.

3.2.6.5 Smoke Point from Watson K and Distillation Data A simplification of Equation (140) gives Equation (141):

$$\ln SP(mm) = -1.028 + 0.474K_W - 0.00168(MEABP) \quad (141)$$

where MEABP is in degrees Rankine.

Equation (140) (now API TDB procedure 2B10.1) turns out to be slightly more accurate than Equation (141), but it is more complex and requires derived knowledge of the MEABP. It can be estimated as a mid-volume (50%) point or VABP, but the resulting accuracy of the equation will be no better than the previous correlation.

3.2.7 Cloud Point, Pour Point and Freeze Point Predictions[89,113,122,155]

These are related measurements and are highly correlated with one another.

3.2.7.1 Cloud Point from Distillation and Gravity Data The API studied a dual-range correlation in this case (Equation 142). The accuracy of either correlation falls off dramatically when it goes out of the temperature ranges shown in Table 24.

Table 23 SP and AP error analysis

	Equation (138)	Equation (139)
Mean boiling range (°F)	297.0–936.0	n/a
SP range (mm)	5.0–42.0	18.5–28.7
AP range (°F)	190.5–644.0	
FP range (°F)	n/a	31.7–187.4
Average absolute error (mm)	216	242
Average error (%)	11.62	9.67
Average bias error (%)	4.10	0.72

$$CP = C_0 + C_1(MEABP)^2 + C_2(MEABP)^{SG} + C_3(SG)^{-1} + C_4(SG)^2 \quad (142)$$

where CP is the cloud point (°F) and MEABP is the mean average boiling point (°F). This is API procedure 2B9.1.

3.2.7.2 Pour Point from Gravity, Molecular Weight and Viscosity Data API Technical Databook 1994 procedure 2B11.1 is represented by Equation (143):

$$PP\ (^\circ F) = 234.95S^A MW^B (V_{100})^C \quad (143)$$

$A = 2.971$, $B = 0.6124 - 0.4376SG$, $C = 0.3103 - 0.8328SG$, SG is the specific gravity, V_{100} = standard 100 °F kinematic viscosity (cSt). See Table 25 for error analysis.

When Equation (132) was run against a database of several hundred waxy crude fractions ($100 < MW < 800$), the average absolute error dropped to ±5.5 °C (10 °F).

3.2.7.3 Freeze Point from Pour Point Data A quick approximation of the PP can be made from either the freeze point (FRP) or the CP of petroleum fractions (Equation 144). The same is true of the other properties, when given one of the three.

$$FRP = 5.252 + 0.9263(PP) \quad (144)$$

where FRP and PP are in degrees Fahrenheit. This is API procedure 2B10.1.

3.2.7.4 Pour Point from Freeze Point Data Equation (145) is just an algebraic manipulation of Equation (144) that works well:

$$PP = 1.079(FRP) - 5.70 \quad (145)$$

where FRP and PP are in degrees Fahrenheit.

Table 24 CI correlation parameters (Equation 142)

CI parameter	Low temp.: $-80\,^\circ F < T < 30\,^\circ F$	Higher temp.: $0\,^\circ F < T < 110\,^\circ F$
C_0	−6583	−14 363
C_1	0.000632	0.000778
C_2	−1.30	−1.832
C_3	3311	−7641
C_4	3862	7676

Table 25 PP error analysis (Equation 143) (temperature range NBP <800 °F, MW range <800)

	For TBP <650 °F	For TBP >650 °F	Combined
Absolute average error(%)	9.6	42.8	28.2
Absolute bias error(%)	−2.6	26.6	15.2

3.2.7.5 Cloud Point from Freeze Point Data The linear Equation (146) gives very good values:

$$\mathrm{CP} = -5.746 + 1.005(\mathrm{FRP}) \tag{146}$$

where FRP and CP are in degrees Fahrenheit.

A second nonlinear equation (Equation 147) will give slightly better results and the extra mathematical complexity is minimal:

$$\mathrm{CP} = 5696 + 3.866(\mathrm{FRP}) - 2329(\mathrm{FRP})^{0.18} \tag{147}$$

where FRP and CP are in degrees Rankine.

An analysis of the errors for Equations (144–147) is given in Table 26. CPs are in the range −80 to 50 °F and FPs are in the range −90 to 50 °F.

3.2.7.6 Freeze Point from Cloud Point Data This is just an algebraic manipulation of Equation (146) above, which works well (Equation 148):

$$\mathrm{FRP} = 0.995(\mathrm{CP}) - 5.715 \tag{148}$$

where FRP and CP are in degrees Fahrenheit.

3.2.7.7 Cloud Point from Pour Point Data This linear function (Equation 149) gives very good values:

$$\mathrm{CP} = 0.9930(\mathrm{PP}) + 4.026 \tag{149}$$

where PP and CP are in degrees Fahrenheit.

This correlation is very accurate at predicting either the CP or PP (see Equation 150), given the other quantity. Correlations on experimental data yielded an absolute average error of approximately 2.25 °C (4.05 °F) and an average bias value of approximately ±0.17 °C (0.3 °F).

3.2.7.8 Pour Point from Cloud Point Data The CP can also be used for the determination of the PP with Equation (150). This equation is just an algebraic manipulation of Equation (149), but is still valid.

$$\mathrm{PP} = 1.007(\mathrm{CP}) - 4.054 \tag{150}$$

where PP and CP are in degrees Fahrenheit.

Table 26 Estimated accuracy of carbon content correlations

Method	Average absolute error (%)	Average absolute bias (%)
Equation (144)	4.00	0.0
Equation (145)	4.39	0.0
Equation (146)	3.97	0.0
Equation (147)	2.91	0.0

Figure 21 PP vs CP intercorrelation.

Equation (150) is best for CPs between 0 and 110 °F and MEABPs of 275–840 °F.

3.2.7.9 Pour Point from Distillation and Viscosity Data The PP can be determined from a combination of distillation and viscosity data or from distillation alone (Equation 151). This is now API TDB procedure 2B8.1.

$$\mathrm{PP} = 753 + 136[1 - \exp(-0.15V_{100})] - 572(\mathrm{SG}) + 0.0512V_{100} + 0.139(\mathrm{MEABP}) \tag{151}$$

where PP and MEABP are in degrees Rankine, V_{100} is the standard viscosity of the fraction at 100 °F in centistokes. If one lacks viscosity data, Equation (152) can be used:

$$\mathrm{PP} = \frac{3.85 \times 10^{-8}(\mathrm{MEABP})^{5.49}}{10^{z}} + 1.4 \tag{152}$$

where $z = 0.712(\mathrm{MEABP})^{0.315} + 0.133\mathrm{SG}$. The units here are identical with those for Equation (151).

3.2.7.10 Freeze Point from Distillation and Gravity Data The FRP can be determined from a combination of distillation and gravity data from API procedure 2B11.1 (Equation 153):

$$\mathrm{FRP} = -2390 + 1826(\mathrm{SG}) + 122.5\,K_{\mathrm{W}} - 0.135(\mathrm{MEABP}) \tag{153}$$

where FRP and MEABP are in degrees Rankine.

3.2.7.11 Cloud Point from Distillation and Gravity Data The CP can be determined from a combination of distillation and gravity data from API procedure 2B12.1 (Equation 154):

$$\log(\mathrm{CP}) = -7.41 + 5.49\log(\mathrm{MEABP}) - 0.712 \times (\mathrm{MEABP})^{0.315} - 0.133(\mathrm{SG}) \tag{154}$$

where CP is the cloud point in degrees Rankine and MEABP is the mean average boiling point in degrees Rankine.

3.2.8 Refractive Index Use and Prediction[9,133]

The RI of a *pure* compound is easily found in any of several handbooks. It is predictable by an equation such as Equations (155) or (156):

$$\mathrm{RI} = \frac{C_0 + C_1}{\mathrm{MW} + C_2} \tag{155}$$

$$\mathrm{RI} = C_0 + C_1\mathrm{MW} + C_2 \tag{156}$$

where RI is the refractive index (sodium D-line) at 68 °F (20 °C) and C_0, C_1 and C_2 are defined in various handbooks. The values of the coefficients are consistent within compound types such as *n*-alkanes, *n*-alkenes, *n*-alkylcyclopentanes, etc.

3.2.8.1 Refractive Index of Hydrocarbon Mixtures from Gravity and Boiling Point Data API Technical Databook (1994) procedure 2B5.1 is represented by Equation (157):

$$F_\mathrm{H} = C_0 \exp[C_1 T_\mathrm{b} + C_2(\mathrm{SG}) + C_3 T_\mathrm{b}(\mathrm{SG})] T_\mathrm{b}^{C_4} (\mathrm{SG})^{C_5} \tag{157}$$

where C_0–C_5 are defined in Table 27, T_b is the MEABP and F_H is the Huang characterization factor. Then (Equation 158)

$$\mathrm{RI} = \left[\frac{1 + 2F_\mathrm{H}}{1 - F_\mathrm{H}}\right]^{0.5} \tag{158}$$

for the RI at 68 °F (see Table 28 for analysis of RI correlation).

3.2.9 The Characterization Factor[103–106]

By far the most universal characterization parameter used in the prediction of hydrocarbon stocks is the Watson *K* factor (K_W). This characterization factor is an important and special physical property of hydrocarbons defined by Equation (159):

$$K_\mathrm{W} = \frac{[\mathrm{CABP}\ (^\circ\mathrm{R})]^{1/3}}{\mathrm{SG}} \tag{159}$$

Table 27 RI correlation parameters

Coefficient	Light fractions[a]	Heavy fractions[b]
C_0	0.0266	0.02341
C_1	0.0003905	0.0006464
C_2	2.468	5.144
C_3	−0.0005704	−0.0003289
C_4	0.00572	−0.407
C_5	−0.720	−3.333

[a] MW 70–300, boiling point range 90–650 °F.
[b] MW 300–600, boiling point range 650–1000 °F.

where the CABP is in degrees Rankine or Kelvin (see section 2 for discussion of boiling point correlations) and SG is the specific gravity at 60 °F.

The characterization factor is a measure of the distribution of different types of molecules (paraffins, naphthenes and aromatics) in a petroleum fraction. The higher the Watson *K* factor, the higher is the paraffinicity; the lower the Watson *K* factor, the higher is the aromatics content. This is similar to the way in which the AP is often used. The AP varies with boiling point, whereas K_W typically does not. For most refinery stocks, K_W varies from 10.0 to 13.0.

In addition, the Watson *K* factor correlates well with many other physical properties, so that when this is known, it is possible to estimate other properties with good accuracy. The following physical properties correlate well with the characterization factor:

- MW
- pseudocritical temperature
- true critical temperature
- pseudocritical pressure
- viscosity
- aniline number
- viscosity index
- hydrogen content
- heat of combustion
- thermal expansion
- enthalpy corrections

The K_W factors of pure hydrocarbons are given in Table 29. The values for most petroleum oils lie between 11.0 and 12.0. A straight-run (''Virgin'') gas-oil might have a K_W of about 11.7, while a cracked gas-oil of similar boiling range might have a K_W of 11.2. Table 30 lists the Watson *K* ranges of some refinery ''straight-run'' product cuts. Table 31 gives Watson *K* ranges of several refinery ''cracked'' product cuts. The characterization factor of a fraction can be determined to within an accuracy of <0.1 and can be used and interpreted with considerable confidence and reliability.

The most accurate way to determine the characterization factor is from the CABP defined by Equation (8). Also shown are the MW and pseudocritical temperature.

The Watson *K* factor may also be estimated from the AP (Figure 19a) and from viscosity–gravity charts.

Table 28 Analysis of RI correlation

	Average absolute error (%)	Average bias error (%)
MW range (70–600)	0.49	−0.11
Boiling point range (90–1000 °F)	0.27	0.05

Table 29 Characterization factors of selected pure hydrocarbons

Component	K_W
Propane	14.7
Butane	13.5
Pentane	13.0
Hexane	12.8
Heptane	12.7
Octane	12.65
Isobutane	13.85
Isopentane	13.00
2-Methylheptane	12.7
2,2-Dimethylhexane	12.65
3-Ethylhexane	12.5
2,2,4-Trimethylpentane	12.55
Benzene	10.2
Toluene	10.1
m-Xylene	10.4
Ethylbenzene	10.4
Propylbenzene	10.65
Butylbenzene	10.8
α-Methylnaphthalene	9.5
Propylene	14.2

Cyclopentane	11.2
Cyclohexane	11.05
Methylcyclohexane	11.4
Ethylcyclohexane	11.45
Butylcyclohexane	11.7
Hexylcyclohexane	11.9
Cyclooctane	10.9

Table 30 Watson *K* characterization factors of straight-run fractions from crude oils, listed according to crude base

Crude type	Low-boiling fractions	High-boiling fractions
Paraffinic	12.2+	12.2+
Paraffinic–intermediate	12.2+	11.4–12.0
Paraffinic–naphthenic	12.2+	11.4–
Intermediate–paraffinic	11.5–12.0	12.2+
Intermediate	11.4–12.1	11.4–12.1
Intermediate–naphthenic	11.4–12.1	11.4–
Naphthenic–intermediate	11.5–	11.4–12.1
Naphthenic–paraffin	11.5–	12.2+
Naphthenic	11.4–	14.4–

Other characterization factors of note are the viscosity–gravity constant (VGC), the Huang factor (F_H) and the refractivity intercept (R). Figure 16 illustrates the value range relationship of K_W and these three other factors to composition of the cut.

Table 31 Watson *K* characterization factors of refinery stocks

Source of stock	API gravity	Watson *K*
Raw absorption gasoline	94.6	13.6
Cracked resid from vapor-phase cracking	8.8	10.4
Natural gasoline:		
California	81.9	12.7
Debutanized E.Texas		12.55
Mid-continent	82.2	12.8
Products of thermal cracking:		
Gasolines	58.5–61.2	11.8–12.0
Gasolines		11.5–11.8
Cracking still feeds		10.5–11.5
Recycle stock		10.0–11.0
Light cycle oil	20.0	10.5
Heavy cycle oil	11.0–14.0	10.4–10.5
Gas-oil: paraffin base crude	32.0	11.8
Gas-oil: naphthene base crude	26.0	11.2
Visbreaker resid	8.8	11.1
Cracked resid	2.6–10.3	10.5–10.7
Cracked resid	4.3	9.5
Cracked resid: vapor phase cracking	8.8	10.4
Products of catalytic cracking:		
Hydroformed gasoline	49.0–51.0	11.4–11.5
Cycle oil, once-through		11.3
Hydrocracked light cycle oil: paraffin base		11.4–11.5
Hydrocracked light cycle oil: naphthenic base		10.8–11.0
Hydrocracked heavy cycle oil: paraffin base		11.0
Hydrocracked heavy cycle oil: naphthenic base		10.2–10.8

Several of the equations presented in section 3 are essentially derivatives of these equations. K_W, however, is still the most widely used characterization factor. One major use of these other factors is the speciation of hydrocarbon cuts by compound type.

The refractivity intercept, *R*, is estimated by Equations (160) and (161):

$$R = 1.0482X_p + 1.038X_n + 1.081X_a \quad (160)$$

$$= n - \frac{SG}{2} \quad (161)$$

The viscosity–gravity constant, *VGC*, is estimated by the Equations (162–164):

$$VGC = 0.774X_p + 0.915X_n + 1.040X_a \quad (162)$$

$$= -1.816 + 3.484(SG) - 0.1156 \ln V_{100} \quad (163)$$

$$= -1.948 + 3.535(SG) - 0.1613 \ln V_{210} \quad (164)$$

where X_p, X_n and X_a are the mole fractions of paraffins, naphthenes and aromatics, respectively, n = sodium D-line RI of liquid at 20 °C, V_{100} is the standard viscosity at 100 °F (cSt) and V_{210} is the standard viscosity at 210 °F (cSt).

The Huang factor is defined by rearranging Equation (157):

$$F_H = \frac{n^2 - 1}{n^2 + 2} \tag{165}$$

Coupled with the fact that $X_p + X_n + X_a = 1.00$, Equations (160–165) and (157) can be solved for relative amounts of P, N and A to within an accuracy of approximately 0.05 fraction.

API procedure 2B4.1 presents another estimation procedure. (Equations 166–168):

$$X_P = A_0 + A_1 R + A_2(VGC) \tag{166}$$

$$X_N = B_0 + B_1 R + B_2(VGC) \tag{167}$$

$$X_A = C_0 + C_1 R + C_2(VGC) \tag{168}$$

Coefficients for Equations (166–168) are given in Table 32.

3.2.10 Molecular Weight[9,118,120,125]

MW can be measured directly in the laboratory, and there are several means of doing so. The problem is that they are slow, require methodical attention and are, therefore, expensive to use in everyday operations. Gel permeation chromatography (GPC) and GC/MS techniques are two of the more common of these methods.

There are, fortunately, some correlations that do a good job of MW assessment with a minimum of experimental data. Two such correlations are presented here.

3.2.10.1 Average Molecular Weight as a Function of Gravity and Boiling Point This is expressed by Equation (169):

Table 32 Coefficients for Equations (166–168)

Constant	70 < MW < 200	200 < MW < 600
A_0	−13.36	2.574
A_1	+14.46	1.013
A_2	−1.413	−3.573
B_0	23.98	2.464
B_1	−23.33	−3.670
B_2	0.8152	1.963
C_0	−9.624	−4.088
C_1	+8.874	2.657
C_2	0.5983	1.610

$$\mathrm{MW} = 20.49\left\{\exp[1.165 \times 10^{-4} T_b - 7.787(\mathrm{SG}) + 1.158 \times 10^{-3} - (T_b)(\mathrm{SG})]\right\}(T_b)^{1.260}(\mathrm{SG})^{4.983} \tag{169}$$

where T_b is the MEABP of the cut (°R) and SG is the specific gravity of the cut.

3.2.10.2 Average Molecular Weight as a Function of Gravity and Viscosity This is expressed by Equation (170):

$$\mathrm{MW} = 223.6(V_{100})^{-1.124+1.123(\mathrm{SG})}(V_{210})^{3.476-3.083(\mathrm{SG})} \tag{170}$$

where V_{100} is the cut viscosity at 100 °F (cSt), V_{210} is the cut viscosity at 210 °F (cSt) and SG is the SG of the cut.

3.2.11 Critical Properties[64,82,86,118,119,121,132,151,187]

Traditional mixture estimation of a "pseudocritical" property is merely a linear molar-ratio average blend of all the components. Nobody likes this very much but no-one has come up with a general procedure that is significiantly better at this time.

3.2.11.1 Critical Temperature as a Function of Gravity For a simple hydrocarbon gas we have (Equation 171):

$$T_c = 94.72 + 170.7(\mathrm{SG}) \tag{171}$$

where T_c is the estimated critical temperature (°C) and SG is the gas specific gravity in relation to air at 60 °F, 1 atm.

For a hydrocarbon liquid with Engler (90–10) slope >0.5 °C %$^{-1}$ (Equation 172):

$$\ln T_c = 3.853 + 0.8799 \ln(\mathrm{SG}) + 0.4293 \ln(\mathrm{MABP}) \tag{172}$$

For a hydrocarbon liquid with Engler (90–10) slope <0.5 °C %$^{-1}$ (Equation 173):

$$\ln T_c = 4.052 + 0.4012(\mathrm{SG}) + 0.379 \ln(\mathrm{MABP}) \tag{173}$$

where T_c is the estimated critical temperature (°C), SG is the standard SG of the liquid at 60 °F and MABP is the molar (not mean) average boiling point temperature (°C).

Another method of predicting hydrocarbon liquid critical temperature is the current API procedure 4D1.1 (Equation 174):

$$T_c = 186.2 + 1.667Z - 0.7127 \times 10^{-3} Z^2 \tag{174}$$

where $Z = (\mathrm{SG})(\mathrm{VABP} + 100)$, T_c is the estimated critical temperature (°F), SG is the standard specific gravity of the liquid at 60 °F and VABP is the volumetric average boiling point temperature (°F).

Equation (174) is accurate to within about a 1% average error.

A third valid method of predicting hydrocarbon liquid critical temperature is the current API procedure 4D3.1 (Equation 175):

$$T_c = 10.64\left\{\exp[-5.175^{-3}T_b - 0.5444(SG) + 3.60\times10^{-3} \times (T_b)(SG)]\right\}(T_b)^{0.8107}(SG)^{0.5369} \quad (175)$$

where T_c is the estimated critical temperature (°R), SG is the standard specific gravity of the liquid at 60 °F and T_b is the MEABP temperature (°R) described in section 2. Equation (175) is accurate to within a 0.8% average error.

It is good in the ranges $70 < MW < 295$, $80 < T_b < 650$ °R and $6 < API < 95$.

3.2.11.2 Critical Pressure as a Function of Gravity and Distillation Data For a hydrocarbon gas (Equation 176):

$$P_c = 48.92 - 4.028(SG) \quad (176)$$

where P_c is the estimated critical pressure (10^5 Pa) and SG is the gas specific gravity in relation to air at 60 °F, 1 atm.

For a hydrocarbon liquid with Engler (90–10) slope >0.5 °C %$^{-1}$ (Equation 177):

$$\ln P_c = 8.18 - 1.931\ln(SG) - 0.8727\ln(MABP) \quad (177)$$

and for a hydrocarbon liquid with Englers (90–10) slope <0.5 °C %$^{-1}$ (Equation 178):

$$\ln P_c = 7.742 + 2.802(SG) - 0.7539\ln(MABP) \quad (178)$$

where P_c is the estimated critical pressure (10^5 Pa), SG is the standard specific gravity of the liquid at 60 °F and MABP is the molar (not mean) average boiling point temperature (°C).

A third valid method of predicting hydrocarbon liquid critical pressure is the current API procedure 4D4.1 (Equation 179):

$$P_c = 6.162\times10^6\left\{\exp[-4.725\times10^{-3}T_b - 4.801(SG) + 3.194\times10^{-3}(T_b)(SG)]\right\}(T_b)^{-0.4844}(SG)^{4.085} \quad (179)$$

where P_c is the estimated critical pressure (psia), SG is the standard SG of the liquid at 60 °F and T_b is the MEABP temperature (°R) described in section 2. Equation (179) is accurate to within a 2.6% average error.

It is good in the ranges: $70 < MW < 295$, $80 < T_b < 650$ °R and $6 < API < 95$.

3.2.11.3 Acentric Factor The acentric factor is an important property that it is necessary to have for the calculation of real and pseudocomponent thermodynamic properties. By definition it is given by Equation (180):

$$w = -\log\left(\frac{P^*}{P_c}\right) - 1.00 \quad (180)$$

where P^* is the vapor pressure of the component at $T = 0.7T_c$, temperature is in degrees Rankine and pressure in psia for Equations (177) and (178).

API TDB procedure 2A1.1 allows one to estimate the acentric factor if the critical temperature and pressure are known (Equation 181):

$$w = \frac{(\ln(P^*/P_c) - 5.927 + 6.096/(T_r)) + (1.289\ln(T_r) - 0.1693(T_r)^6)}{(15.25 - 15.69/(T_r)) - (13.47\ln(T_r) - 0.4368(T_r)^6)} \quad (181)$$

where P is the vapor pressure of the component at reduced temperature $T_r = 0.7T_c$. $T_r = T/T_c$.

3.2.12 Thermal Capacities and Transport Properties[9,94,129]

3.2.12.1 Heat of Combustion An important property of all fuels is the heat of combustion, since this is a measure of the energy available from the fuel. ASTM D-240 is the basis used for the direct determination of heats of combustion of aviation gasolines and of fuel oils.

There is an indirect method of calculating or estimating the net heat of combustion of gasolines. The calculation is based on the diesel index (DI) defined according to Equation (182):

$$DI = \frac{(AP)(API\ Gravity)}{100} \quad (182)$$

with (Equation 183)

$$\text{Net Btu lb}^{-1} = 17\,608 + 20.5DI - 7.24\times10^{-2}(DI)^2 \quad (183)$$

where the AP is in degrees Fahrenheit.

3.2.12.2 Liquid Enthalpy (Reduced Temperature and Pressure $T_r < 0.8$, $P_r < 0.98$) API procedure 12B3.1 provides a way of estimating the enthalpy of an unspeciated liquid hydrocarbon mixture (Equation 184):

$$H_L = A_1(T - 259.7) + A_2[T^2 - (259.7)^2] + A_3[T^3 - (259.7)^3] \quad (184)$$

where: H_L is the liquid enthalpy in Btu lb^{-1} T (°F) is the temperature of interest and (Equations 185–187)

$$A_1 = 10^{-3}\left(-1171 + (23.72 + 24.91SG)K_W + \frac{(1150 - 46.54K_W)}{SG}\right) \quad (185)$$

$$A_2 = 10^{-6} \quad (1.0 + 0.8246\,K_W)\left(56.09 - \frac{13.82}{SG}\right. \tag{186}$$

$$A_3 = -10^{-9} \quad (1.0 + 0.8246)\left(9.676 - \frac{2.365}{SG}\right. \tag{187}$$

3.2.12.3 Vapor Enthalpy ($T_r > 0.8$, $P_r > 0.98$) API procedure 12B3.1 provides a way of estimating the enthalpy of an unspeciated hydrocarbon vapor mixture in equilibrium with a saturated liquid (Equation 188):

$$H_L = H_L^* + B_1(T - 0.8T_{pc}) + B_2(T^2 - 0.64T_{pc}^2) + B_3 \times (T^3 - 0.512T_{pc}^3) + RT_{pc}[4.507 + 5.266w] \tag{188}$$

where H_v is the saturated (at dew point) vapor enthalpy in Btu lb^{-1}, H_L is the saturated (at bubble point) liquid enthalpy at temperature T in Btu lb^{-1}, B factors are given by Equations (189–191):

$$B_1 = 10^{-3}\left\{-356.4 + 29.72K_w + B_4 \quad 295.0 - \frac{248.5}{SG} \right\} \tag{189}$$

$$B_2 = 10^{-6}\left\{146.24(77.62 - 2.772K_w) - B_4 \quad 301.4 - \frac{253.9}{SG} \right\} \tag{190}$$

$$B_3 = -10^{-9}\{56.49 - 2.95B_4\} \tag{191}$$

$$B_4 = 10^8\left\{\frac{12.8}{K_w - 1}\left(1.0 - \frac{10.0}{K_w} \quad (SG - 0.885) \times (SG - 0.70)\right\}^2 \right. \tag{191A}$$

For $10.0 < K_w < 12.8$ and $0.70 < SG < 0.885$, else $B_4 = 0$.

T (°F) is the temperature of interest, W is the acentric factor, T_{pc} is the pseudocritical temperature (see section 3.12) in degrees Rankine, $T_r = T/T_{pc}$ is the reduced temperature (dimensionless) and R is the standard gas constant, 1.986 Btu (lb^{-1} mol^{-1}R^{-1}).

3.2.12.4 Isobaric Liquid Heat Capacity of Petroleum Fraction Liquids ($T_r > 0.8$, $P_r > 0.98$) The isobaric (constant pressure) heat capacity of a liquid petroleum fraction is relatively independent of the pressure itself owing to the small compressibility of the liquid. For reduced temperatures below 0.9 (Equation 192):

$$C_p = X_0 + X_1T + X_2T^2 \tag{192}$$

where (Equations 193–195)

$$X_0 = -1.171 + [0.237 + 0.0249(SG)]K_W + \frac{1.150 - 0.04654\,K_W}{SG} \tag{193}$$

$$X_1 = 10^{-4}(1.0 + 0.8246\,K_W)\left(1.122 - \frac{0.2763}{SG}\right. \tag{194}$$

$$X_2 = 10^{-8}(1.0 + 0.8246\,K_W)\left(2.903 - \frac{0.7096}{SG}\right. \tag{195}$$

and T is temperature in degrees Rankine.

3.2.12.5 Isobaric Vapor Heat Capacity of Petroleum Fraction Vapors ($T_r > 0.8$, $P_r > 0.98$) The isobaric (constant-pressure) heat capacity of a vapor-phase petroleum fraction is valid except in the immediate range of criticality (Equation 196):

$$C_p = X_0 + X_1T + X_2T^2 + (\text{pressure correction}) \tag{196}$$

where (Equations 197–200)

$$X_0 = -0.3654 + 0.2972\,K_W + X_3\left(0.2950 - \frac{0.2485}{SG}\right. \tag{197}$$

$$X_1 = -10^{-4} \quad 2.925 - (1.552 - 0.05543\,K_W)K_W + X_4\left(\frac{6.028 - 5.069}{SG}\right. \tag{198}$$

$$X_2 = 10^{-7}[1.695 + 0.0844X_3] \tag{199}$$

$$X_3 = \left(\frac{12.8}{K_W - 1.0} \quad \left(\frac{1.0 - 10}{K_W} \quad (SG - 0.885) \times (SG - 0.70)(10^4)\right.\right.$$
$$\text{for } 10.0 < K_W < 12.8 \text{ and } 0.70 < SG < 0.885$$
$$= 0 \text{ for all other values of } K_W \text{ and SG} \tag{200}$$

and T = temperature in degrees Rankine.

The pressure correction term is a somewhat complex calculation which is beyond the scope of this article. It is zero below about 50 psi and is generally insignificant compared with the error of the correlation below the 150–300 psia range. For higher vapor pressures, any number of good thermodynamic texts will cover the proper use of this factor.

3.2.12.6 Thermal Conductivity – Liquid

Method 1. Liquid Thermal Conductivity as a Function of Molecular Weight. API procedure 12B3.1 provides a way of estimating the enthalpy of an unspeciated hydrocarbon vapor mixture in equilibrium with a saturated liquid (Equation 201):

$$k = \left(C_0 + \frac{C_1}{MW} + \frac{C_2}{MW^2} \quad + T\left(\frac{C_3 + C_4}{MW} + \frac{C_5}{MW^2}\right.\right. \tag{201}$$

where k is the thermal conductivity of the liquid at temperature T, in units of Btu (lb h °F ft^{-1})$^{-1}$ for

temperature in degrees Fahrenheit, $C_0 = 0.01335$, $C_1 = 0.2463$, $C_2 = 1.149$, $C_3 = 3.277 \times 10^{-5}$, $C_4 = 4.188 \times 10^{-5}$ and $C_5 = 0.001843$.

Method 2. Liquid Thermal Conductivity as a Function of Boiling Point. API procedure 12A3.1 provides a way of estimating the enthalpy of an unspeciated hydrocarbon vapor mixture in equilibrium with a saturated liquid (Equation 202):

$$k = (\text{MEABP})^{0.2904}(9.961 \times 10^{-3} - 5.364 \times 10^{-6}T) \quad (202)$$

where k is defined as above and MEABP is the mean average boiling point of the liquid cut.

3.2.12.7 Thermal Conductivity – Vapor API procedure 12A3.2 provides a way of estimating the enthalpy of an unspeciated hydrocarbon vapor mixture in equilibrium with a saturated liquid (Equation 203):

$$k = 0.07577 - 4.1 \times 10^{-5}T \quad (203)$$

where k is defined as above.

3.2.12.8 Viscosity – Liquid Although often a primary inspection property, the viscosity of petroleum cuts is often estimated or is correlated with other variables to quantize derivatives for determining the interrelational effects of change in a property.

Method 1. Liquid Viscosity as a Function of Temperature. API procedure 11A4.1 provides a way of estimating the liquid viscosity of an unspeciated hydrocarbon as a function of any temperature, T (°F) (Equation 204):

$$\text{Log (viscosity)} = B\left(\frac{539.7}{T + 459.7}\right)^2 - 0.8696 \quad (204)$$

where B and S are given by Equations (205) and (206):

$$B = \log V_{100} + 0.8696 \quad (205)$$

$$S = 0.2801 \log V_{100} + 1.862 \quad (206)$$

and V_{100} is the standard liquid viscosity at 100 °F.

Method 2. Liquid Viscosity as a Function of Boiling Temperature. API procedure 11A4.2 is another way of estimating the liquid viscosity of an unspeciated hydrocarbon. One needs slightly more information on the distillation data to use this procedure.

For standard viscosity at 100 °F (Equations 207–209):

$$V_{100} = V_{\text{ref}} + V_{\text{cor}} \quad (207)$$

$$\log V_{\text{ref}} = -1.356 + 8.161 \times 10^{-4}T_{\text{b}} + 8.385 \times 10^{-7}T_{\text{b}}^2 \quad (208)$$

$$\log V_{\text{cor}} = A_1 + A_2K_{\text{W}} \quad (209)$$

where (Equations 210 and 211):

$$A_1 = 34.93 - 0.08844T_{\text{b}} + 6.735 \times 10^{-5}T_{\text{b}}^2 - 1.014 \times 10^{-8}T_{\text{b}}^3 \quad (210)$$

$$A_2 = -2.926 + 0.006984T_{\text{b}} - 5.100 \times 10^{-6}T_{\text{b}}^2 + 7.494 \times 10^{-10}T_{\text{b}}^3 \quad (211)$$

T_{b} is the MEABP of the liquid cut, in degrees Rankine, and V_{100} is the standard liquid viscosity at 100 °F (cSt).

For standard viscosity at 210 °F (Equation 212):

$$\log V_{210} = -1.924 + 2.411 \times 10^{-4}T_{\text{b}} + 0.5113 \log(T_{\text{b}}V_{100}) \quad (212)$$

where T_{b} is the MEABP of the liquid cut, in degrees Rankine, V_{100} is the standard liquid viscosity at 100 °F (cSt) and V_{210} is the standard liquid viscosity at 210 °F (cSt).

3.2.12.9 Density – Liquid Although usually a quick and easy primary inspection property, densities of petroleum cuts are often estimated or correlated with other variables to evaluate derivatives for determining the interrelational effects of change in a property.

Method 1. Liquid Density as a Function of Molecular Weight and Refractive Index. API procedure 2B4.1 provides a way of estimating the liquid density of an unspeciated hydrocarbon as a function of MW and RI (Huang index) (Equation 213).

$$D = 2.831\,\text{MW}^{0.3975}\,F_{\text{H}}^{1.1354} \quad (213)$$

where F_{H} is given by Equation (214):

$$F_{\text{H}} = \frac{n^2 - 1}{n^2 + 2} \quad (214)$$

n is the RI at 68 °F.

Method 2. Liquid Density as a Function of Standard Viscosity. API procedure provides a way of estimating the liquid density of an unspeciated hydrocarbon as a function of standard viscosity measurements (Equation 215):

$$\text{SG} = 0.7717\,V_{100}^{0.3975}\,V_{210}^{1.1354} \quad (215)$$

where SG is the liquid specific gravity, V_{100} is the standard liquid viscosity at 100 °F (cSt) and V_{210} is the standard liquid viscosity at 210 °F (cSt).

4 PROPERTY PREDICTION FOR MIXTURES OF KNOWN INDIVIDUAL VALUES

4.1 Introduction

The characterization of a typical petroleum stock is normally based on easily and routinely obtained inspection

data. How does one handle the case where two stocks, for which a specific inspection property is known for each, are blended? One could estimate average values of gravity and boiling point from some standard mixing rules. For example, gravities blend well linearly with weight percentage or linearly with the inverse of the volume percentage. TBPs blend less well volumetrically but usually give usable results when treated so. With these two quantities, most mixture properties can be estimated. The problem with this technique is that another layer of estimation error has been placed upon the results. Attempts to use simple (i.e. linear) mixing rules to correlate blended values of a hydrocarbon property with the individually estimated or measured blend stock values of the same property have shown marginal results at best.

This difficulty has been overcome by the use of a blend index function and blending numbers, which will be described in this section.

4.2 Blending Index and Numbers

A blend index is a mathematical transformation of a numerical value which can then be blended with other transformed stock values (of the same item) in a reasonably simple algebraic form. The value of the property after transformation is known as the blend number.[50]

Once the blend number of the mixed stream has been calculated, the actual property value of the blended stream can be determined by performing the inverse of the index transform.

Among the values that are best determined for mixtures in this fashion are viscosity, CP, PP, RVP, FP and AP. Suggested blend index transforms (f^{T}), mixing and retransform ($f^{-\mathrm{T}}$) functions for some of these properties are typically of the form in Equations (216–218):

$$\text{index}_I = f^{\mathrm{T}}(\text{property_value})_I \tag{216}$$

$$\text{property_number}_{\text{mix}} = \text{SUM}[(\text{index}_I) \times (\text{vol_pctg_of_stock})_I] \tag{217}$$

$$\text{property_value}_{\text{mix}} = f^{-\mathrm{T}}(\text{property_number}_{\text{mix}}) \tag{218}$$

where I is the index of blend stocks from 1 to N = number of stocks. $f^{\mathrm{T}}(\ )$ and $f^{-\mathrm{T}}(\ )$ are the chosen property value transform and inverse transform functions, and vary greatly in form from one property to another. The forms presented here are those which have been published and are generally used by the petroleum refining community based on commonly available information. The user may want to use custom/proprietary data to modify the blend index function and its numerical parameters, but the forms shown here are generally the best that the author has found for this purpose.

Table 6 shows a series of gasoline blend components and their corresponding properties. The great majority of blend prediction problems in today's refineries involve gasoline stocks. The important values under EPA [Environmental Protection Agency (US)] Phase II/CARB spec fuels are RVP and distillation values, especially D-$86_{90\%}$. The other blend methods described in this section, such as CP and PP, are more applicable to jet fuels and heavier stocks.

4.2.1 Viscosity Blend Number

The viscosity blend number (VBN) is best used with volume averaging, i.e. (Equation 219):

$$\text{VBN}_{\text{average}} = \text{SUM}[(\text{VBN}_I)(\text{volume_pctg_of_stock})_I] \tag{219}$$

where I is the index of blend stocks from 1 to N = number of stocks.

4.2.1.1 Index for Viscosity Blending Number at Set Measurement Temperatures[50] VBN is defined according to Equation (220):

$$\begin{aligned}\text{VBN(at } T_{\text{ref}}) = -[&(-0.04375\text{API} + 0.333\,K_{\text{W}} + 1.467) \\ &\times \log(T_{\text{ref}}) - \log(T_{\text{vis}})] \\ &+ \log[\log(\text{viscosity}_{(\text{CS})} + 0.7)]\end{aligned} \tag{220}$$

where API is the API gravity and $\text{viscosity}_{(\text{CS})}$ and T_{vis} are any laboratory-measured pair of viscosity (centistokes) and temperature (degrees Rankine). Typical viscosity measurement standards are taken at 100 °F or 40 °C, 150 °F or 66 °C and 212 °F or 100 °C. *(Do not forget to convert the temperatures to absolute form before calculating the blend number.)*

The viscosity update/transform function to Equation (220) is Equation (221):

$$\text{viscosity}_{\text{mix}} = [\text{VBN(at } T_{\text{ref}}) + 0.54] \times \frac{K_{\text{W}}}{T_{\text{ref}} - 355} \tag{221}$$

Separate calculations are required for each standard reference temperature. The values for 100, 140 and 212 °F will, for example, have different blend numbers.

4.2.1.2 General Blend Indices at Various Temperatures A general VBN that can be used at any standard T_{vis} is given by Equation (222):

$$\text{VBN} = \frac{\log[\log(\text{viscosity}_{\text{cSt}} + 0.6)] - 0.834}{0.00265} + 154 \tag{222}$$

Table 33 VBNs of a typical gas–oil stream

Cut point mid (vol.-%)	VBN (via Equation 206) at mid (vol.-%)		
	40 °C	66 °C	100 °C
7.93	141.9	30.8	Out of range
30.39	281.5	173.8	18.21
50.9	383.6	282.1	135.3
70.36	465.4	383.7	234.7
76.2	494.6	393.4	281
81.35	Out of range	437.0	319

where viscosity_{cSt} is the measured centistokes at a standard reference temperature (40, 66 or 100 °C).

In the absence of a large amount of data, this method is reasonably good for relating any viscosity measured at any temperature. The VBN method presented here provides only for the prediction of viscosities at the standard temperatures. To determine viscosity at intermediate temperature, one needs to interpolate (extrapolate at your own risk!) from the curve generated at three standard points.

The cut point viscosity data in Table 33 were obtained from a West Texas light vacuum gas-oil (LVGO) cut. Inaccuracies at the extremes of data are common and should be used with caution.

4.2.1.3 Log-linear Blend Function If no explicit blend data are available, a reasonable guess for the viscosity of a blend of streams, all taken at or referenced to the same temperature, can be estimated by blending the logarithm of the viscosities linearly with equivalent volume fractions of the cuts and retransfoming the average by taking the antilogarithm of the value calculated.

4.2.2 Aniline Point Blends[50]

The aniline point (AP) index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (223–225):

$$\text{AP_index}_I = \exp(0.003652 \times \text{aniline_point}_I) \quad (223)$$

$$\text{AP_index}_{\text{mix}} = \text{SUM}[(\text{AP_index}_I) \times (\text{volume_pctg_of_stock})_I] \quad (224)$$

where I = blend stock index for 1 to N = number of stocks and

$$\text{aniline_point}_{\text{mix}} = \frac{\log(\text{AP_index}_{\text{mix}})}{0.003652} \quad (225)$$

4.2.3 Cloud Point Blends[81]

The cloud point (CP) index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (226–228):

$$\text{CP_index}_I = \left(\frac{\text{cloud_point}_I}{600}\right)^{20} \quad (226)$$

$$\text{CP_number}_{\text{mix}} = \text{SUM}[(\text{CP_index}_I) \times (\text{volume_pctg_of_stock})_I] \quad (227)$$

where I is the index of blend stocks from 1 to N = number of stocks and

$$\text{cloud_point}_{\text{mix}} = (600 \times \text{CP_number}_{\text{mix}})^{0.05} \quad (228)$$

where cloud_point is measured in absolute form (degrees Rankine for the equations above).

4.2.4 Pour Point Blends[24,80]

4.2.4.1 Method 1 PP index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (229–231):

$$\text{PP_index}_I = \left(\frac{\text{pour_point}_I}{600}\right)^{12.5} \quad (229)$$

$$\text{PP_index}_{\text{mix}} = \text{SUM}[(\text{PP_index}_I) \times (\text{volume_pctg_of_stock})_I] \quad (230)$$

where I is the index of blend stocks from 1 to N = number of stocks and

$$\text{pour_point}_{\text{mix}} = (600 \times \text{PP_number}_{\text{mix}})^{0.08} \quad (231)$$

where pour_point is measured in degrees Rankine.

4.2.4.2 Method 2 An alternative function that the author has used successfully is given by Equations (232) and (233):

$$\text{PP_index}_I = \left(\frac{\text{pour_point}_I}{280.6}\right)^{9.0909} \quad (232)$$

$$\text{pour_point}_{\text{mix}} = (280.6 \times \text{PP_number}_{\text{mix}})^{0.11} \quad (233)$$

where pour_point is measured in degrees Rankine.

4.2.4.3 Method 3: American Society for Testing and Materials D-97 ASTM D-97 specifies a blend transform function of the following form in Equation (234):

$$(\text{pour_point}_{\text{mix}})^{C_0} = \text{SUM}(V_I^{C_1} T_I^{C_2}) \quad (234)$$

where I is the index of blend stocks from 1 to N = number of stocks and C_0, C_1 and C_2 are coefficients defined in Table 34.

Table 34 Coefficients for ASTM D-97 mixing rule

PP range (°C)		C_0	C_1	C_2
Low	High			
9	51	11.76	0.99	11.76
−12	21	16.67	1.145	16.67
−21	−6	10.87	1.105	10.87

4.2.5 Reid Vapor Pressure Blends[9]

RVP index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (235–237):

$$\text{RVP_index}_I = (\text{RVP}_I)^{1.25} \tag{235}$$

$$\text{RVP_number}_{\text{mix}} = \text{SUM}[(\text{RVP_index}_I) \times (\text{volume_pctg_of_stock})_I] \tag{236}$$

where I is the index of blend stocks from 1 to N = number of stocks and

$$\text{RVP}_{\text{mix}} = (\text{RVP_number}_{\text{mix}})^{0.8} \tag{237}$$

Of all blended properties, the RVP correlation has the most variation in accepted parameters. Literature values for the index exponent range from 1.07 to 1.32. The user may want to use a customized index function, but a 1.25 index is generally a safe number to start with.

The individual blend values must all correspond to the same blend temperature, 37 °C (100 °F), if following normal standards.

4.2.6 Distillation Temperature Blends

Several methods of blending TBPs can be derived from the procedures in section 2.

ASTM distillation values cannot be accurately blended in any kind of linear fashion if the range of initial to final boiling point of the cut is greater than about 200 °F. This eliminates the heavier cuts altogether and is not a recommended procedure for the lighter cuts either.

A better procedure is to generate the TBP curve for each stock and blend the values based on either volume or weight percentage recovery, depending upon which was used as the independent data acquisition variable. Alternatively, one may take relative volumes of all blend streams at an equivalent boiling point cut and blend these together on a similar pro rata basis. The accuracy of either method is about the same.

The very best TBP blend method is to blend the streams linearly based on the temperature–molar fraction percentage function, but this is a rather complex calculation, and the extra accuracy is often not worth the extra effort. A compromise method comes from the API Technical Data Book,[9] which suggests that TBP values be turned into a molar-based "mean-average" boiling point temperature for a cut fraction. These values are assumed to be linearly blendable at the standard volume fraction recoveries at 10, 30, 50, 70% and 90%.

For wide fraction cuts in general, the API method is recommended. For narrow cuts, simple TBP blending is usually justified.

4.2.7 Flash Point Index Blends[50]

FP index blends linearly with the relative volume of each stock. The two most useful index, mixing, and retransformation functions are as follows.

4.2.7.1 Method 1. Hu–Burns Protocol[81] This is the most commonly used method in industry today (Equations 238–240):

$$\text{FP_index}_I = \left(\frac{735.8}{\text{flash_point}_I}\right)^{19.61} \tag{238}$$

$$\text{FP_number}_{\text{mix}} = \text{SUM}[(\text{FP_index}_I) \times (\text{volume_pctg_of_stock})_I] \tag{239}$$

where I is the index of blend stocks from 1 to N = number of stocks and

$$\text{flash_point}_{\text{mix}} = \left(\frac{\text{FP_number}_{\text{mix}}}{735.8}\right)^{0.051} \tag{240}$$

where flash_point is measured in degrees Rankine.

4.2.7.2 Method 2. Whickey–Chittenden Protocol
This is the current API Technical Data Book procedure 2B15.1 (Equations 241–243):

$$\log(\text{FP_index}_I) = -6.119 + \frac{4345}{\text{flash_point}_I + 383.0} \tag{241}$$

$$\text{FP_number}_{\text{mix}} = \text{SUM}[(\text{FP_index}_I) \times (\text{volume_pctg_of_stock})_I] \tag{242}$$

where I is the index of blend stocks from 1 to N = number of stocks and

$$\text{flash_point}_{\text{mix}} = \frac{4345}{\log(\text{FP_number}_{\text{mix}} + 6.119)} + 383.0 \tag{243}$$

where flash_point is measured in degrees Rankine.

4.3 Other Blend Prediction Methods

4.3.1 Dissolved Gas Effects on Viscosity

One of the most important property estimates that are made incorrectly are liquid viscosity calculations

when dissolved gases are present, even if in known amounts. API Technical Databook procedure 11A7.1 presents a reasonable approach to handling this problem (Equations 244 and 245):

$$\frac{V_m}{V_a} = \frac{(0.294\text{GLR} + 137V_a^{1/3} + 538.4)^3}{[V_a^{1/3}(0.871\text{GLR} + 137 + 538.4)]^3} \quad (244)$$

$$V_t = -1.209 + \frac{1.209 + \log(137V_m)}{T + 139} \quad (245)$$

where V_m is the viscosity (centipoise) of the gas-saturated liquid at 100 °F (37.8 °C), V_a is the viscosity (centipoise) of the gas-free liquid at 100 °F (37.8 °C), V_t is the viscosity (centipoise) of the gas-saturated liquid at any Fahrenheit temperature, GLR is the gas–liquid ratio (std. $ft^3\ Bbl^{-1}$) or liquid and T is the temperature at which the viscosity value is desired (degrees Fahrenheit).

4.3.2 Derived Property Blend Rules

Several blend values of streams with calculated or derived properties can be quickly estimated as blends fractionally prorated to volume, weight or molar bases. Among these are the following:

- Watson K (K_W) – blend is linearly prorated on component weight fraction;
- acentric factor – blend is linearly prorated based on component weight fraction;
- (pseudo)critical temperature – blend is linearly prorated based on component molar fraction;
- (pseudo)critical pressure – blend is linearly prorated based on component molar fraction.

4.3.3 Miscellaneous Property Index Blend Rules of Thumb

It is obvious that prediction of mixture properties is as much art as science. There is no ''right'' way to generate a blending method. There are a few generalizations, however, that can be listed.

- Critically examine any experimental data that are not monotonically inclined in the direction that one would expect. For example, densities and viscosities of liquids tend to decrease with increasing temperature. It should not have any anomalies over the range of data or one could imply that there is a constraint on its usage (above critical point, bad data, etc.).
- Use a transform method that has a mathematical inverse.
- Base the blend mix on either the dependent (first choice) or independent data acquisition variable. Use derived values for the blending vectors with care. The exception is for intrinsic properties that are based on a relative amount of sample. This would include heating value (Btu per weight unit) or density (weight per volume unit). If the dependent data acquisition value does not correspond to the denominator of the property value units, then one might be well advised to make this transform before blending. The heating value, for example, will be very accurate if estimated on a weight percentage proration, even if the data are based on a volume percentage recovery.
- Try to use a linear blend function. This can be done by proper selection of the transform function. Use of higher ordered blending rules often leads to localized anomalies in the generation of the property–index matrix. These anomalies will probably not correspond to the real world and can drastically disrupt the use of such blend functions in planning, real-time control and optimization operations.

GLOSSARY OF TERMS

Alkane	Hydrocarbons conforming to the formula C_nH_{2n+2} with no saturated bonds or heteroatoms in the molecular structure.
Antiknock Index	Synonym for octane rating.
Aromatics	Hydrocarbons with at least one fully saturated ring structure, but with no heteroatoms in the molecular structure
ASTM Distillation	A set of standard procedures governing petroleum distillations. Usually a synonym for ASTM D-86 procedures, sometimes for D-1160.
Atmospheric Resid	The remainder or bottoms of the crude feed to a distillation column that runs at or near atmospheric pressure. Most of the lighter cuts have been taken off in the tower.
Catalytic Reformate	The product of a reaction process that changes naphthene rings into aromatics. Product changes low octane cut to high octane cut.
Coker/Coking	The process/tendency of a hydrocarbon, under thermal stress, to crack and form a mostly carbon solid phase, with simultaneous evolution of some lighter fluid hydrocarbon components

Conversion Reactor	A chemical process in a refinery that cracks and provides subsequent processing such as hydrogenation and distillation for separation of cuts.
Conversion Refinery	A refinery that has one or more conversion reactors. Typically, most sizeable refineries have at least three of the following units: catalytic cracker, coker/ thermal cracker, hydrotreater (usually several), hydrocracker, catalytic reformer.
Cracked	The condition of having long hydrocarbon chains thermally or catalytically broken. In lighter components, the result is often one or more unsaturated bonds between some carbons. In heavier stocks, a mostly carbon (called coke) phase forms with devolution of some lighter hydrocarbons. Thermal cracking is an endothermic process.
Crude Unit	Synonym for the tower/column (or series of same) that first processes crude oil feed to a refinery.
Cut	The name given to a distillation product that is a ''cut'' of the crude feed. Alternatively, it refers to the measured amounts of analyte that come off the column in specified boiling point or TBP ranges.
D-2887 Distillation	The ASTM standard most often associated with GC analysis of petroleum wide-cut boiling ranges.
Diesel	The cut or fraction of a crude that is used as fuel for compression–ignition engines.
FCC	Acronym for fluid catalytic (''cat'') cracker.
Fluid Catalytic Cracking	The process whereby diesel and gas-oil range hydrocarbons are vaporized cracked with the aid of a heterogeneous catalyst at high temperature. The coke formed in the process is subsequently burned to provide the thermal energy necessary to drive the reactions.
Fraction	Synonym for cut.
Gas-oil (atm, vacuum)	The fraction of a crude feed that is too heavy for diesel fuel and still comes off the column at a higher temperature. It generally makes an excellent feed for FCC and hydrocracker units.
Gasoline	The cut or fraction of a crude that is currently used as fuel for internal combustion engines.
GC	Acronym for gas chromatography.
Hydroprocessing	The process whereby diesel and gas-oil range hydrocarbons are vaporized and cracked in the presence of a hydrogen-rich environment with the aid of a heterogeneous catalyst at high temperature. Very little coke is formed in the process and most unsaturated components are saturated. Depending upon the severity, even aromatics can be hydrogenated.
Hypothetical Component	The name given to the lumping of several dozen to hundreds of individual species of hydrocarbons and related organic compounds into a single TBP boiling range. It can vary from using one to several ''hypothetical'' compound to represent the entire collection of species.
Kerosine	The standard name for the cut or fraction of a crude that is currently used as fuel for turbine engines or for campfire fuel. It is slightly heavier than gasoline, but much less volatile and dangerous for handling by humans.
Light Ends	The name for an accumulation of very light (lighter than gasoline) collection of hydrocarbons in a distillation column. Alternatively, this term refers to the lighter (as defined by boiling point) few percent of any distillation curve.

Multivariate	The use of several types of analysis and characterization of petroleum cuts and fractions to arrive at some sort of speciation of the components, at least by type if not by actual accounting. It involves solution of multiple equations with matrix coefficients taken from several different data sources.
Naphtha (Light, Heavy)	Gasoline and kerosine boiling range material. Light naphtha refers to the gasoline components, and heavy naphtha refers to the compounds with boiling points nearer the kerosine range. Usually it is synonymous with the top two or three product cuts from the crude unit.
Naphthenes	Alkanes possessing one or more cyclic but unsaturated rings.
Octane	The tendency of a naphtha fuel to pre-ignite or ''knock'' in an internal combustion engine.
Paraffin	Popular synonym for alkane, also for aliphatic.
Prefrac Column	A sometimes used device that strips a crude of its lighter naphtha cuts before heating the crude to maximum temperature.
Pseudo-component	Synonym for hypothetical component
Real Time	The protocol whereby data about a process are obtained, analyzed and utilized in the control of that process within a short period of time, well under the time constant of the process frequency response function.
Reduced Crude	The term for either atmospheric resid or for crude that has been run through a prefrac column to remove a significant portion of its lighter naphtha content.
Resid	The remainder or bottoms of the crude feed to a distillation column that runs at or near atmospheric pressure. Most of the lighter cuts have been taken off in the tower.
Stabilizer	The common term for a distillation column that is used to strip off very light ends from a hydrocarbon cut in order to make a product specification or safety related reason.
Straight Run	Synonym for virgin cut as applied to physical distillation fractions.
TBP Distillation	The generic term for refluxed laboratory distillation that approximates the ''TBP'' of a petroleum cut or fraction. ASTM D-2892 is ostensibly the standard, but there are so many variations as to make an ''official'' standard superfluous.
Thermal Cracking	The process whereby heat is applied to a hydrocarbon, resulting in its ''cracking''. Delayed cokers work on what is called a ''heat soak'' process whereby heavy hydrocarbon cuts will crack noncatalytically if a high enough temperature is maintained in the reactor for a long enough time. One of the products is coke, hence the name ''coker''.
Topping Refinery	A refinery whose sole purpose is to recover fuel quality material by distillation and hot flashing of crude/vapor feeds. No conversion reactors, except for perhaps a coker unit, are found in this type of refinery.
Tower/Column	The piece of process equipment that is used to separate hydrocarbons on the basis of boiling points by use of a heat source driving all vapors upward and refluxing/condensing the heavier cuts downward by liquid gravity flow. A modern refinery contains dozens of columns. The first unit that a crude feed usually sees is the crude unit, which typically consists of one to three columns operating at different pressure levels.

Transport Properties	The physical properties of a substance that are the primary quantities involved in the characterization of mass, momentum and heat transfer in industrial hydrocarbon processing operations.
Transport Fuels	The naphtha and diesel range cuts that provide the primary bulk of liquid fuels for current domestic transportation methods using some form of a combustion engine, internal combustion, turbine or compression–ignition.
Vacuum Resid	The remainder or bottoms of the crude feed to a distillation column that runs at far below atmospheric pressure. It contains most of the lighter cuts that were not taken off in the atmospheric column. It allows vaporization of components at a lower temperature than at atmospheric pressure, thus reducing the chance of thermal cracking and coking during the processing.
Virgin	Naturally occurring as found in the feed crude oil and not having been processed in a conversion (chemical) reactor. Physical processing such as distillation is acceptable for this nomenclature as long as the chemical structure is not changed.

ABBREVIATIONS AND ACRONYMS

AG	Aniline Gravity Constant
AP	Aniline Point
API	American Petroleum Institute
ASTM	American Society for Testing and Materials
ATM	Atmospheric
BMCI	Bureau of Mines Correlation Index
BS & W	Bottom Sediment and Water
CABP	Cubic Average Boiling Point
CARB	California Air Resources Board
CC	Conradson Carbon Number
CGSB	Canadian General Standards Board
CI	Cetane Index
CN	Cetane Number
CP	Cloud Point
DI	Diesel Index
EFV	Equilibrium Flash Vaporization
EPA	Environmental Protection Agency (US)
FP	Flash Point
FRP	Freeze Point
GC	Gas Chromatography
GC/IR	Gas Chromatography/Infrared
GC/MS	Gas Chromatography/ Mass Spectrometry
GLR	Gas–Liquid Ratio
GPC	Gel Permeation Chromatography
HDA	Hydrodealkylation
HPLC	High-performance Liquid Chromatography
IR	Infrared
LSR	Light Straight Run
LVGO	Light Vacuum Gas-oil
MABP	Molar Average Boiling Point
MEABP	Mean Average Boiling Point
MS	Mass Spectroscopy
MW	Molecular Weight
NBP	Normal Boiling Point
NMR	Nuclear Magnetic Resonance
PONA	Paraffins, Olefins, Naphthenes and Aromatics
PP	Pour Point
RC	Ramsbottom Carbon Number
RI	Refractive Index
RVP	Reid Vapor Pressure
SD or Simdist	Simulated Distillation
SG	Specific Gravity
SP	Smoke Point
TBP	True Boiling Point
USBM	United States Bureau of Mines
VABP	Volumetric Average Boiling Point
VBN	Viscosity Blend Number

Pharmaceuticals and Drugs: Introduction

R.K. Gilpin
Wright State University, Dayton, USA

1 Organization and Information 2
2 Biographical Sketch of the Authors 3
3 Conclusion and Future Trends 5
Abbreviations and Acronyms 5

The field of pharmaceutical analysis includes a wide range of analytes, varying in structure from very simple compounds to complex biomolecules. As such, a host of approaches have been and continue to be used in developing reliable analytical methodology for these analytes. In the broadest sense, there are two types of procedures: those that are designed as simple, reliable means of monitoring formulated products in terms of their identity, strength and quality, and those that are used during the drug discovery and development stages to answer numerous and fundamentally more challenging questions related to safety, therapeutic effectiveness, drug stability and purity, as well as in helping to develop better understanding of the biomechanisms and kinetics.

From the economic standpoint, there is the continuing pressure to reduce production and hence product costs, and from the quality assurance side to develop methods that are more reliable, accurate, and sensitive. Over the last thirty years there has been an increasing reliance on separation-based methods combined with various pre-analysis sample clean-up procedures such as solid phase or supercritical fluid extraction and post-column approaches like derivatization fluorescence detection or electrospray mass spectrometry (MS) to improve their accuracy and sensitivity.

From the regulatory standpoint, an important change that occurred in the United States during the late 1970s was the introduction of Good Laboratory Practices by the Federal Drug Administration. These regulations were the direct result of several perceived problems in the pharmaceutical industry and they resulted in greater accountability in terms of calibration, maintenance and record keeping. With the emergence of an expanding number of multinational companies and increasing global markets, similar trends and demands have followed throughout the world.

From the hardware/equipment standpoint, two of the significant changes that have occurred have been miniaturization and automation. Modern and important techniques that have emerged in the last three decades that have had an important impact on modern pharmaceutical analysis include high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), high-field solution and solids nuclear magnetic resonance (NMR), electrospray MS, and computer automation and robotics. Likewise, in terms of sample handling, solid-phase extraction, supercritical extraction and micro-capillary dialysis sampling have also become important tools.

As the direct result of the above pressures and trends, the increasing competitiveness of the marketplace, and the quest for less expensive, safer, and better drugs with well understood and targeted activities, the pharmaceutical industry has been and continues to be one of the leaders in pioneering new analytical methods. This is easily documented by the thousands of published accounts that appear yearly in the scientific literature, the growth in the job market for those obtaining undergraduate degrees in chemistry and graduate degrees in analytical and allied fields of chemistry, and the growth in vendors marketing analytical hardware and speciality items.

Unfortunately, a ''down-side'' of the remarkable growth in the field of chemical analysis and the automation of modern analytical instrumentation and procedures has been a greater isolation of the analyst from the fundamental principles governing the measurement being made. There are many excellent methods published daily, but, on the negative side, there are numerous accounts that have appeared which are based on what might be considered less than reliable conditions. Generally, most practicing analytical chemists understand how to make their hardware perform effectively, and they have a reasonable empirical/working knowledge of how to systematically change conditions in order to produce a given result, but they sometimes either fail to consider or choose to ignore relatively simple fundamental concepts that influence the reliability and ruggedness of their methods. Many of the problems associated with assay instability result from poorly designed procedures that may appear to provide the correct result but are not optimized to minimize variability. Thus, it is the intent of the current section to address the field of pharmaceutical analysis from both the technique and the topic standpoints. There are articles included that are based on particular techniques, that are topical in nature, and, in a few cases, that survey/review the literature from an accounts perspective. A brief overview of each of these follows.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

1 ORGANIZATION AND INFORMATION

Alkaloids, Pharmaceutical Analysis of. The alkaloid article provides a historical perspective and topical overview of the analysis of more common and pharmaceutically important, naturally occurring bases. It also includes, in tabular form, a review of representative methodology that has appeared in the literature over the last decade.

Antibiotics, Pharmaceutical Analysis of. The antibiotics article provides a brief introduction to the six major classes of antibiotics, the cephalosporins, penicillins, quinolones, streptomyces, sulfonamides and tetracyclines, as well as several other important miscellaneous compounds such as chloramphenicol, isoniazid and trimethoprim. It also includes extensive tables which contain a survey of the recent literature in terms of the analytical methodology that has been introduced for assaying the six major cases of antibiotics.

Chemical Reagents and Derivatization Procedures in Drug Analysis. Derivatization is often used to improve sensitivity or volatility for analytes measured respectively using liquid or gas chromatography (GC). As such, this article provides a discussion of some of the important derivatization procedures used in combination with either liquid chromatography (LC) or GC.

Chiral Purity in Drug Analysis. With the increasing demand for more effective and targeted drugs, the number of assays for evaluating chiral purity has been expanding. The focus of this article is to provide an overview of approaches currently being used to purify chiral drugs and to measure their enantiomeric purity. Regulatory matters also are discussed.

Combinatorial Chemistry Libraries, Analysis of. The advent of modern combinatorial synthetic methods has made it possible to produce dozens of potential leads in a single experiment. Because of this, there is an expanding demand for rapid and sensitive methods to analyze these compounds. This article discusses important aspects of the topic, including the use of high throughput strategies and approaches for handling small quantities of analytes.

Eluent Additives and the Optimization of High-performance Liquid Chromatography Procedures. LC is by far the single most widely used technique for assaying pharmaceuticals, and in a majority of the reported LC methods, the separations are carried out under reversed-phase conditions. This article presents an overview of important considerations in the selection of eluent additives and addresses why and how they are used to optimize the chromatographic separations.

Gas and Liquid Chromatography, Column Selection for, in Drug Analysis. Two of the most important analytical techniques used in pharmaceutical analysis are GC and LC. At the heart of each of these techniques are reliable and selective columns. This article provides useful information related to column selection.

Mass Spectrometry in Pharmaceutical Analysis. MS has been an important analytical tool in pharmaceutical analysis for many years, and it is the premier gas chromatographic detection technique in terms of sensitivity and specificity. Unfortunately, many early attempts at coupling MS with LC were less successful. However, over the last decade, the development of modern electrospray technology combined with multi-dimensional (i.e. MS/MS and MS/MS/MS) mass spectrometric analysis has made it an important and operationally functional tool. This article considers various aspects of the use of modern instrumentation for the analysis of pharmaceutically important peptides.

Nuclear Magnetic Resonance Spectroscopy in Pharmaceutical Analysis. With the introduction of modern high-field NMR instrumentation and the ability to carry out multi-dimensional and solids experiments, uses of the technique have expanded beyond its important role as the major structural elucidation technique. This article discusses the application of modern NMR techniques in the pharmaceutical field, including its uses in evaluating enantiomeric purity.

Planar Chromatography in Pharmaceutical Analysis. On a historical basis the use of planar (i.e. thin layer) chromatographic methods has always been an important topic in pharmaceutical analysis. Assays based on this technique have served as quick and convenient means of screening compounds for purity and in evaluating their stability as a function of storage conditions. The current article focuses on important topics related to the analysis of pharmaceutical compounds, using modern planar chromatographic approaches.

Proteins and Peptides Purification in Pharmaceuticals Analysis. Interest in the potential use of proteins, protein fragments, and peptide drugs has increased over the last decade. One of the more important analytical aspects of this work has been to develop reliable and convenient means of preparing sufficient quantities of a candidate compound for testing. This article discusses purification approaches useful for these types of compounds.

Quantitative Structure–Activity Relationships and Computational Methods in Drug Discovery. Since the beginning of the modern pharmaceutical industry, the quest for methods of predicting a compound's activity and toxicity from structural features in the molecule have been sought. Although the ability to calculate a many-body problem with the superposition of all of the conformational and motional dynamics is still not possible, much has been done in this area, and the current article discusses important aspects and uses of modern computational approaches in drug discovery.

Robotics and Laboratory Automation in Pharmaceuticals Analysis. This current article addresses important hardware and validation considerations related to the automation of modern pharmaceutical analysis. Likewise, examples of the application of automated and robotic procedures for various dosage forms are given.

Solid-phase Extraction and Clean-up Procedures in Pharmaceutical Analysis. Often the most difficult and time-consuming part of an analysis is rendering the analyte in a form that can be conveniently measured using either a classical or instrumental approach. Sample clean-up is often a topic that is ignored or minimized, but may be the major pitfall in carrying out a successful analysis. The current article addresses important aspects of modern sample preparation, including solid-phase extraction and supercritical fluid extraction.

Steroid Analysis. Steroids represent an important class of compounds that are used to treat a variety of health problems. In many cases, adequate detection is one of the more demanding aspects encountered in developing appropriate analytical methodology. The current article discusses a variety of chromatographic, electrochemical, and spectrometric techniques used to assay steroids, and it presents methodology to evaluate them by therapeutic class.

Vibrational Spectroscopy in Drug Discovery, Development and Production. Modern infrared (IR) spectroscopy has become an increasingly important technique in drug discovery, especially as it relates to product development and production monitoring. This article addresses important instrumental and operational aspects of its use, including different sampling and acquisition techniques.

Vitamins: Fat and Water Soluble, Analysis of. Vitamins fall into two major groups, those that are fat soluble and those that are water soluble. In a number of cases (i.e. the fat-soluble vitamins), very subtle structural differences exist that require relatively demanding separation conditions to obtain the desired assay specificity. The current article considers various analytical procedures that have been developed for each of the two broad vitamin groups.

2 BIOGRAPHICAL SKETCH OF THE AUTHORS

A.P. Argekar: Reader in Chemistry, Institute of Science, University of Mumbai, India. B.S. Karnataka University, M.S. and Ph.D., University of Mumbai, India. Recipient of the Indian Drug Manufacturer's Best Paper Award in 1996. Research interests include pharmaceutical analysis, environmental science, and separation techniques.

L.C. Bailey: Professor of Pharmaceutical Chemistry, Department of Pharmaceutical Chemistry, Rutgers University, Piscataway, NJ. B.S. (1957) Chemistry, Fordham University, NY, M.S. (1965) and Ph.D. (1969) Analytical Chemistry, Rutgers University, NJ. Research interests include analysis of drugs in dosage forms, biochemical analytical methods development, stability of pharmaceutical preparations, standardization of pharmaceutical packaging materials.

J.J. Bao: Senior Scientist, Procter and Gamble Pharmaceuticals, Inc., Cincinnati, OH, and Adjunct Professor of Chemistry at Shandong University, Jinan, China. Ph.D. (1993) Analytical Chemistry, Purdue University, Indiana. Research interests include HPLC, HPCE (high-performance capillary electrophoresis), micro-total analysis systems, high-throughput electrophoretic separations, and various detection techniques, such as MS and laser induced fluorescence.

A.T. Balaban: Professor of Organic Chemistry, Bucharest Polytechnic University, Romania. Ph.D. Chemical Engineering and Dr. Habil. (1974) in Organic Chemistry, Polytechnic University, Bucharest, Dipl. Radiochemist, Bucharest University and Institute of Atomic Physics, Bucharest. Research interests include synthesis of heterocyclics, stable nitrogen free-radicals, nitric oxide donors, catalytic isomerizations of polycyclic aromatic hydrocarbons (PAHs), isotopically labeled compounds, theoretical and computational methods related to drug design, chemical applications of graph theory, topological indices, and molecular modeling.

C.J. Bates: Head of Micronutrient Status Research, MRC Human Nutrition Research Laboratory, Cambridge, UK. B.A. (1961) Biochemistry, Oxford University, M.A. and Ph.D. (1964) Oxford University, Post-Doctoral Fellow (1964–66) Yale University School of Medicine. Research interests include human requirements and status indices for micronutrients, especially vitamins.

P. Campíns-Falcó: Titular Professor of Analytical Chemistry, University of Valencia. B.S. (1981) Chemistry, Ph.D. (1985) Chemistry, University of Valencia, Valencia, Spain and Postdoctoral Fellow (1982–84), University of Valencia. Research interests include new methods of calibration and data interpretation, automated development of analytical chemical methods (multidimensional chromatography and flow injection analysis), global methods of analysis in several matrixes, and testing and correction of systematic bias error.

N.D. Danielson: Professor of Chemistry, Miami University, Oxford, OH. B.S. (1972) Chemistry, Iowa State University, M.S. (1974) Analytical Chemistry, University of Nebraska, and Ph.D. (1978) Analytical Chemistry, University of Georgia. Research interests include CE, HPLC, microflow injection analysis, and chemiluminescence.

B. Dawson: Research Scientist, Health Canada, Ottawa, ON, Canada. B.S. (1972) and M.S. (1974) Chemistry from St. Francis Xavier University, Nova Scotia, Ontario,

Ph.D. Chemistry (1981), Carleton University, Ontario, and Postdoctoral Fellow (1982) University of Western Ontario. Research interests include NMR studies of drugs and related materials, structure elucidation of pharmaceutical impurities, degradation products, and metabolites, illicit and ''designer'' drugs, and natural products, and the applications of NMR spectroscopy for the determination of isomeric content of drugs.

L.P. Dudones: Research Scientist, Ricerca, Inc., Painesville, OH. B.S. (1992) Chemistry, Hiram College, OH, and Ph.D. (1998) Analytical Chemistry, Kent State University, OH. Research interests include chromatographic and NMR studies of chemically modified surfaces, elucidation of chromatographic mechanisms, and HPLC methods development for pharmaceutical analysis.

K. Duff: R&D Supervisor, HPLC Products, Restek Corporation, State College, PA. B.A. (1979) Chemistry, Lycoming College, PA. M.S. (1982) Organic Synthesis/Biochemistry, Rensselaer Polytechnic Institute, NY. Research interests include the development and characterization of novel chromatographic media such as a new line of ''Allure'' LC/MS phases, ''Ultra'' HPLC packings, and numerous other HPLC packing materials and columns.

J.W. Finn: Senior Scientist/Laboratory Head, Genetics Institute. B.S. (1971) University of Minnesota, Minneapolis, MN, Ph.D. (1981) Analytical Chemistry, Kansas State University.

P.A. Gallagher: Research Chemist, Environmental Protection Agency, Cincinnati, OH. B.S. (1993) Chemistry, Thomas More College, KY and Ph.D. (1998) Analytical Chemistry, Miami University. Research interests include HPLC, CE, and inductively coupled plasma/mass spectrometry (ICP/MS).

C.S. Gilpin: Research Librarian, Ohio University Eastern. B.S. (1990) and MLS (1992) Library and Information Science, Kent State University St. Clairsville, OH. Research interests include scientific information retrieval, analytical, pharmaceutical and biomedical information, data management and search systems.

R.K. Gilpin: Professor and Dean of the College of Science and Mathematics, Wright State University, Dayton, OH. B.S. (1969) Chemistry, Indiana State University; Ph.D. (1973) Analytical Chemistry, University of Arizona. Editorial Board Member, *Journal of Chromatographic Science*, and NIH Technology Transfer SSS Member. Research interests include the development of chemically modified surfaces for chromatography, organometallic surface reactions, separation of pharmaceutically and biomedically active compounds, NMR and IR studies of modified surfaces and other ordered systems, and characterization of materials.

D.R. Goodlett: Research Scientist, Department of Molecular Biotechnology, University of Washington, Seattle, WA. B.S. (1982) and M.S. (1988) Auburn University, AL, Ph.D. (1991) Biochemistry, North Carolina State University, and NORCUS Postdoctoral Fellow (1991–1992) Battelle-Memorial Institute, Columbus, OH. Research interests include protein structure–function relationships at the molecular level, development of methods to study signal transduction pathways through mapping of protein phosphorylation sites, and characterization of proteomes both qualitatively and quantitatively.

C.J. Hann: Senior Scientist, Research Division, Solutia, St. Louis, MO. B.S. (1977) Chemistry, Bradley University, IN, Ph.D. (1988) Analytical Chemistry, Kent State University, OH. Research interests include optimization of separation methodology, development of quality assurance procedures for pharmaceutically and biomedically active leads, and process control analysis.

R. Herráez-Hernández: Instructor, Analytical Chemistry, University of Valencia, Valencia, Spain. B.S. (1989) Chemistry, and Ph.D. (1992) Chemistry, University of Valencia. Research interests include the analysis of organic compounds, especially by chromatographic techniques, including multi-dimensional procedures and chiral analysis.

C.E. Kibbey: Group Leader, Separations Group, Analytical Research, Parke-Davis Pharmaceutical Research Ann Arbor, MI. Ph.D. (1993) Analytical Chemistry, University of Michigan. Research interests include the application of HPLC and CE methods development to support drug discovery, characterization of combinatorial libraries for identity and purity, preparative purification of important lead compounds, measurement of physicochemical properties and laboratory automation.

C. Molins-Legua: Instructor of Chemistry, University of Valencia, Valencia, Spain. B.S. (1989) Biochemistry, Ph.D. (1994) Analytical Chemistry, University of Valencia, and FPI Postdoctoral Fellow (1995–1997) R.I.V.M. Research interests include analysis of organic compounds in various matrixes, especially by chromatographic procedures.

Y. Machida: Research Scientist, Analytical Chemistry Department, Product & Technology Development Laboratory, Tanabe Seiyaku Co. Ltd., Osaka, Japan. B.S. (1989), M.S. (1991), and Ph.D. (1998) Pharmacy, Nagoya City University. Research interests include synthesis and characterization of novel chiral stationary phases for drug analysis.

H. Nishi: Research Scientist, Analytical Chemistry Department, Product & Technology Development Laboratory, Tanabe Seiyaku Co. Ltd., Osaka, Japan. B.Tech. (1980), M.Tech. (1982), and Ph.D. (1991) Pharmacy, Kyoto University; Young Pharmaceutical Scientist Award from the Kinki Division of the Pharmaceutical Society of Japan in 1994 and a member of the Editorial

Board of the *Journal of Chromatography A*. Research interests include the separation of enantiomeric drugs by HPLC and CE.

N. North: Team Leader for new automation technology, SmithKline Beecham Pharmaceuticals, UK. Research interests include automation using robotics to develop noninvasive methods for process control.

L.A. Pachla: B.S. (1970) Chemistry, Lawrence Technological University Michigan; Ph.D. (1975) Analytical Chemistry, Purdue University, Indiana. Past member of the Editorial Board of Biomedical Chromatography. Research interests include robotics, electroanalytical chemistry, chromatography, pharmacokinetics, drug metabolism, and bioanalytical chemistry of proteinaceous drugs.

N.G. Pinto: Professor of Chemical Engineering, University of Cincinnati, Cincinnati, OH. B.Tech. (1980) Indian Institute of Technology, M.S. (1982) and Ph.D. (1985) Chemical Engineering, Pennsylvania State University. Research interests include: adsorption and ion exchange chromatography, bioseparations, and the development of novel microsensors.

A. Sevillano-Cabeza: Instructor of Analytical Chemistry, University of Valencia, Valencia, Spain. B.S. Chemistry (1976) and Ph.D. (1983) University of Valencia. Research interests include kinetic analysis and the analysis of organic compounds in various matrixes, especially by chromatographic procedures.

S.A. Tomellini: Associate Professor, Department of Chemistry, University of New Hampshire, Durham, NH. B.S. (1979) University of Rhode Island, Ph.D. (1985) Rutgers University, Visiting Scientist 1991–1992, Laser Biophysics and Spectroscopy Section, Laboratory of Chemical Physics, NIH. Research interests include expert systems in analytical chemistry, FTIR, HPLC, CE, chemical separations, and IR spectroscopy of lipids.

3 CONCLUSION AND FUTURE TRENDS

From the chemical/biological standpoint the more recent introduction of genetic and combinational methods has resulted in and will continue to result in the production of more novel compounds in shorter periods of time. This, in many respects, is like *The Tale of Two Cities*, in that they represent ''the best of times'' for synthetic chemists, since many potential leads can be produced quickly, and ''the worst of times'' for their analytical counterparts, in that large numbers of samples will need to be assayed using relatively small quantities of materials. Separation techniques like microcolumn HPLC and CE, coupled with highly specific and sensitive detection methods like electrospray ionization mass spectrometry (ESIMS), will continue to become more and more important. Likewise, improvements in hardware are making ESIMS more reliable and user friendly, and miniaturization and probe design are making other highly specific techniques like NMR more feasible as on-line detection methods.

ABBREVIATIONS AND ACRONYMS

CE	Capillary Electrophoresis
ESIMS	Electrospray Ionization Mass Spectrometry
GC	Gas Chromatography
HPCE	High-performance Capillary Electrophoresis
HPLC	High-performance Liquid Chromatography

Although alkaloids are naturally occurring bases, additional generalizations are difficult because they include a wide range of structurally dissimilar compounds. They vary greatly in their chemical and physical properties as well as in their distribution in nature. In some cases certain alkaloids are associated with only a single species of plant, whereas others are more widely distributed between biological groupings of plants, and yet others are found in a wide range of unrelated plants. Likewise, the concentration of a particular compound may be highly localized within a given region of one plant and found predominantly in a different region of another plant. In some cases the levels of an alkaloid may be relatively high and its isolation as a natural product may be economically feasible, whereas in other cases the levels may be extremely low and less commercially desirable. The medicinal use of alkaloids in the form of crude plant extracts has been known for several thousand years and today there are hundreds that have been isolated and characterized. However, very few of them are accepted therapeutically and many of these fit into the broad categories of cinchona, ergot, opium, rauwolfia, tropane, vinca and xanthine alkaloids.

1 INTRODUCTION

1.1 General Information

As a major class of compounds, alkaloids are naturally occurring bases with a wide range of structures, chemical and physical properties, and pharmacological activities. The use of alkaloids as medical agents in the form of crude plant powders and extracts predates the modern pharmaceutical industry by almost four millennia and in some instances prior to modern science, mass poisonings have resulted from their inadvertent usage. This was especially prevalent in Europe during the Middle Ages.

Historically, a primary source of many alkaloids has been flowering plants, although they may be found throughout nature, such as the ergot alkaloids in the grain fungus *Claviceps purpurea*. The first crude alkaloid extract to be studied chemically was opium, which is derived from the latex of the poppy *Papaver somniferum*.[1] Although the initial characterization work on opium that led to the isolation of morphine was carried out in the early 1800s, its use as an analgesic and its narcotic properties had been known for centuries before this.

There are often complex relationships between the alkaloids and their occurrence in nature. In some cases, certain alkaloids such as morphine are associated with only a single species of plant, whereas others like *l*-hyoscyamine are more widely distributed between biological groupings of plants, and yet others (e.g. nicotine) are found in a wide range of unrelated plants.[2] Likewise, the concentration of a given compound may be highly localized within a given area of a particular plant, such as in its leaves, bark, or roots, and this same alkaloid, if present in a different plant, may be found predominantly in another region. In some cases the levels of an alkaloid may be relatively high and its isolation as a natural product may be economically feasible, whereas in other cases the levels may be extremely low and less commercially desirable. A more in-depth discussion of the above items may be found elsewhere.[1–3]

Although today there are several thousand alkaloids that have been isolated and identified structurally, this article will focus only on a relatively small number that are considered to be pharmaceutically more important in terms of their accepted therapeutic value. Some of these compounds are among the earliest alkaloids identified for their medicinal effects, such as morphine, brucine, caffeine, quinine, cinchonine and colchincine.

1.2 Common Properties

Although most alkaloids are crystalline colorless solids, some of the more complex conjugated compounds such as berberine may be colored or, like quinine, fluorescent. A common chemical feature of the alkaloids are that they are bases, which is the basis for many of the commonly used colorimetric methods and thin-layer chromatography (TLC) spray reagents. These are based on the reaction of either organic (e.g. ninhydrin) or inorganic (e.g. Mayer's and Dragendorff's) reagents with the alkaloid to form highly colored products. Beyond this, additional generalizations are more difficult. Structurally, the basic nitrogen or nitrogens (which vary greatly in number and basicity) may be found in a variety of structural environments and hence the equilibrium properties and hydrophobic characteristics vary dramatically between alkaloids.

Illustrated in Figures 1–7 are some of the significant structural differences between a number of the more common pharmaceutically important alkaloids. Nicotine, which is distributed throughout the plant kingdom, is a relatively small molecule with two heterocyclic nitrogens. Similarly caffeine, another widely distributed small molecule, contains four heterocyclic nitrogens but it also contains two additional carbonyl functionalities. Because of their widespread presence and usage, there have been numerous methods developed for assaying both nicotine and caffeine in their natural states and in a host of different formulations and products (Gilpin and Pachla[4–7] and past biannual reviews in this series). Other alkaloids such as berberine, colchicine, and morphine contain only a single nitrogen but are either structurally more complex and/or contain other polar functionalities. For example, the two hydroxyl groups on morphine have a significant influence on its chromatographic properties. Because of these significantly different structural features, the overall ease of analyzing alkaloids and their pharmacological activity vary greatly.

As a result of their basicity, many alkaloids are thermally and photolytically labile, especially in the presence of oxygen. Common breakdown products are the corresponding N-oxides. In the case where the alkaloids contain other reactive groups they may undergo a variety of other reactions and rearrangements. Hydrolysis is often common. As such, during stability testing it is important to evaluate the pharmaceutical products for these likely decomposition candidates. In many cases some of these products, as well as other naturally occurring minor alkaloids and related impurities, may be extremely difficult or impossible to distinguish from the target analyte using simple nonseparation-based analytical procedures. Although details concerning the chemical reactivity of the various classes of alkaloids are presented below, more extensive treatments of this topic may be found elsewhere.[1–3] Commonly, alkaloids, like other organic bases, are stabilized via conversion to their corresponding inorganic or organic salts (i.e. hydrochloride or citrate salts).

1.3 Trends in Analytical Methodology

For over two decades (Gilpin and Pachla[4–7] and past biannual reviews in this series) separation-based procedures have been, and continue to be, the most often used methods for assaying alkaloids and their formulated products. This is consistent with the same trends in other areas of pharmaceutical analysis and often is essential in developing stability-indicating and purity-profiling methods. During this time a variety of techniques have been employed, ranging from simple screening procedures based on the use of an initial thin-layer separation (Table 1[8,9]) in combination with a colorimetric spray reagent (e.g. iodoplatinate, Dragendorff–Munier & Macheboeuf, iodine–potassium iodide reagents[10]) to more elaborate sample pretreatment and work-up procedures in combination with either an isocratic or a gradient elution high-performance liquid chromatography (HPLC) separation. In the latter

instance, assays based on reversed-phase conditions are the most commonly used methods and the most often used eluent additives are simple buffers that are added to control the protonation/deprotonation of the basic nitrogen(s) and hence their retention properties. An in-depth discussion of the influence of eluent pH on solute retention is considered in the article **Eluent Additives and the Optimization of High-performance Liquid Chromatography Procedures** in this publication.

For many of the alkaloids, one of the more commonly encountered problems in developing reliable reversed-phase assays is peak tailing. This problem often is exacerbated when more than one nitrogen is present in the alkaloid and/or the alkaloid contains other polar subsitutents. Peak tailing is the result of residual silanol groups that are present on the reversed-phase packing. Because silica is an amorphous material, the number and distribution of these groups change depending on the synthetic route that is employed to produce the silica,[11,12] which in turn dramatically influences the nature and performance of the reversed-phase packings.[13] To the practicing chromatographer, this problem manifests itself as manufacturer-to-manufacturer and batch-to-batch differences in column performance for a given stationary phase. Additionally, this problem is exacerbated for solutes that have polar functional groups that can interact strongly with residual silanols such as amines and heterocyclics, which are common structural features of alkaloids. In order to minimize the residual silanol problems, one of four approaches are generally used: postreaction end-capping; preparation of sterically blocking phases; electronic manipulation of the attached surface groups; and the use of mobile phase additives. The first three of these approaches are controlled by the manufacturer and are important considerations when purchasing a column, especially for strongly interacting solutes like some of the alkaloids. Although the performance of commercially available bonded phases has improved dramatically, there are still many reversed-phase applications where residual silanol activity leads to unacceptable chromatograms in terms of severely tailing peaks, and as columns age the problem of exposed silanol groups increases even for high-performance bonded phases. Many of these unwanted effects can be eliminated or at least minimized through the use of secondary mobile phase additives. Such problems usually can be addressed by the addition of compounds to the eluent that dynamically modify the surface by a competitive sorption mechanism and hence act to suppress undesirable interactions that can arise between basic solutes and residual silanols. The agents used to do this are strongly sorbing compounds (i.e. molecules that contain a polar head group and a nonpolar tail) that do not interfere with detection. The most commonly used compounds to mask silanol activity and hence to improve peak symmetry are alkylamines,[14] however, in a few cases other compounds (e.g. perfluororalkyl surfactants) have been employed.[15] Alkylamines also are used to enhance the performance of normal-phase separations both in terms of HPLC procedures and in terms of routine TLC screening methods (Table 1).

2 GENERAL INFORMATION AND ANALYTICAL METHODS

2.1 Cinchona Alkaloids

The medicinal value of this group of alkaloids has been known since the 17th century, when crude extracts from cinchona bark, a plant species indigenous to the Andes, were first used for the treatment of malaria.[1,2] Although there have been more than two dozen cinchona alkaloids that have been isolated and identified, four of the pharmaceutically more important compounds are quinine, quinidine, cinchonidine and cinchonine. The structures of these are given in Figure 1. They are made up of two parts: a quinoline nucleus and a quinuclidine moiety. Of these, quinine and quinidine are the primary alkaloids of various species of *Cinchona* and *Remijia* and are present at levels of 1–4% and 0.3–3%, respectively.[16]

Upon oxidation, quinine, quinidine, cinchonidine and cinchonine are converted to the corresponding ketones and they undergo acetylation to form O-acetyl derivatives that reconvert to the starting material on hydrolysis. The vinylic group is susceptible to acid attack and rearrangements. In the case of quinine and quinidine, this tendency is greater than it is for the methoxy group. Greater details

Figure 1 Common cinchona alkaloids.

concerning the chemical reactivity and related properties of these compounds may be found elsewhere.[1,2]

Typically, the cinchona alkaloids are white solids that form sparingly water-soluble mono-salts or highly water-soluble bis-salts. One of the more distinctive spectral features is their fluorescence in acidic media, which has been used in their direct spectrofluorimetric determination as well as by HPLC in combination with fluorimetric detection. Each of these alkaloids has two sites of protonation with respective pK_1 and pK_2 values in the 5.1–5.8 and 9.7–10.0 ranges.[16] When assayed using reversed-phase HPLC conditions, these are the structural features that must be appropriately controlled in order to obtain optimum separation performance.

A representative listing of some of the many methods published for the more common cinchona alkaloids is presented in Table 2.[17–40]

2.2 Ergot Alkaloids

Historically, the medical value of some of the ergot alkaloids has been known for over 3000 years. They are the oldest known mycotoxins and are found in the *Claviceps purpurea*, a filamentous fungus that grows on rye and other gramineaceous crop plants. During the Middle Ages in Europe, ergot poisoning through their vasconstriction and/or hallucination actions was a common occurrence. In a single epidemic in AD 944 it has been reported that about 20 000 people in France died from ingesting ergot-infested flour.[1]

A common structural feature of many of the ergot alkaloids is their tetracyclic ergoline nucleus, as illustrated

Figure 2 Common ergot alkaloids.

in Figure 2. Although all contain an indole structure, some of the clavine compounds, for example, chanoclavine-I and -II and rugulovasine A and B, may contain fewer rings and some of the more complex compounds, for example, the peptide alkaloid ergotamine, contain additional ring systems. The ergot alkaloids can be divided into four subgroups: the clavine alkaloids; the lysergic acid derivatives; the lysergic acid amides; and the ergot peptide alkaloids. Some of the more common compounds are chanoclavine-I (a precursor of agroclavine and elymoclavine), ergonovine, ergotamine and *d*-lysergic acid.

The most commercially important ergot compounds belong to the peptide subgroup. Typically these compounds must be protected from air oxidation, light, and heat. They hydrolyze to form lysergic acid, proline, a second amino acid, an α-keto acid and ammonia. In the case of ergotamine, a compound used for its antimigraine properties, the hydrolysis products are lysergic acid, proline, L-phenylalanine, pyruvic acid and ammonia.[1] The ergot alkaloids form colored products with sulfuric acid and a characteristic blue product with *p*-dimethylaminobenzaldehyde. In many cases a double bond is present at either the 8,9-position (e.g. agroclavine, chanoclavine-I and -II, and paspalic acid) or the 9,10-position (e.g. ergotamine, penniclavine, setoclavine, and *d*-lysergic acid) (Figure 2). These differences can be distinguished in their respective ultraviolet (UV) spectra where λ_{max} is at 284 nm for the indole structure (i.e. the $\Delta^{8,9}$ compounds) and at 318 nm for the 4-vinyl indole structure (i.e. the $\Delta^{9,10}$ compounds). This difference in UV properties between the two types of structures for the $\Delta^{8,9}$ and $\Delta^{9,10}$ alkaloids can be used in combination with variable or dual-wavelength detection to impart additional specificity to HPLC-based methods.

A representative listing of some of the methods published for the more common ergot alkaloids is presented in Table 3.[41–48]

2.3 Opium Alkaloids

The opium alkaloids have been studied more than any other group.[16] They are derived from the latex of a single species of the poppy *Papaver somniferum* and consist of several closely related compounds, including codeine, morphine, neopine, oripavine, and thebaine. Of these, morphine is the most abundant. A second related group of morphinandienone bases include sinomenine and hasubanonine, metaphenine, and protometaphenine. These latter alkaloids are found in Japanese *Sinomenium* and *Stephania* plants.[1] The structural difference between these two groups of compounds is shown in Figure 3.

The first compound to be isolated in pure form from crude opium extracts was morphine, by Serturner in 1805, although 2 years prior to this Derosne had reported the separation of a mixture of morphine and noscapine. The presence of these compounds occurs in nature at levels of 4–21% and 4–8%, respectively.[1] Subsequently, codeine was isolated in 1833. This latter compound also can be produced easily via O-methylation of the phenolic group in morphine. Likewise, codeine can be oxidized at this same position to form the corresponding ketone, codeinone, which also results from the acid hydrolysis of thebaine.[3] In general the morphinandienones can undergo two types of acid-catalyzed rearrangements, forming either aporpines or dibenzazonines. The synthesis and various reaction pathways of this group of compounds are well established.[1–3]

Typically the morphinandienones have UV maxima at 235–240 and 275–280 nm. However, for sinomenine, where the double bond at the 4,5-position is missing, the λ_{max} is at 232 and 265 nm. The mass spectrometric,

spectroscopic and chromatographic properties of the opium alkaloids have been studied by numerous investigators and they are generally easily analyzed via a variety of techniques. A representative listing of some of the many methods published for the more common opium alkaloids is presented in Table 4.[49–98]

2.4 Rauwolfia Alkaloids

Although approximately 150 species of plants belong to the *Rauwolfia* genus, *R. serpentina*, a plant found in India, is the most important member. However, other species such as *R. vomitoria* and *R. tetraphylla*, which are found respectively in Africa and Central America, have become alternative sources. Likewise, synthetically produced reserpine now competes favorable in price with the natural product.[1] The medicinal use of extracts from this family of plants, like the ergot alkaloids, has been known for about 3000 years but the major active compound reserpine, which occurs at about the 1% level, was not isolated and identified until 1952. Other minor (i.e. at about the 0.1% range) alkaloids that belong to this class are ajmalicine, ajmaline, rescinnamine, reserpiline, and yohimbine (see Figure 4).

Like the ergot alkaloids, a common structural feature of the rauwolfia alkaloids is the indole nucleus, as illustrated in Figure 4. Alkaline hydrolysis of reserpine, the principal alkaloid of this class, produces reserpic acid, 3,4,5-trimethoxybenzoic acid, and methanol. Vigorous oxidation of the resulting reserpic acid leads to loss of the indole structure via production of 4-methoxy-*N*-oxalylanthranilic acid.[2]

2.5 Tropane Alkaloids

Tropane alkaloids occur in a variety of *Erythroxylaceae*, *Solanaceae* and *Convolvulaceae* plants, which include *Atropa belladona*, *Datura stramonium*, *Erythroxylon coca*, and *Hyosyamus niger*. The most common compounds in this group are cocaine, *l*-hyoscyamine and its racemized form atropine, hyoscine, scopolamine, and meteloidine (Figure 5). The early use of the tropane alkaloids can be traced to the 16th century both in Europe and South America, where crude preparation of *Atropa belladonna* and dried coca leaves were used, respectively, as medical aids. However, their isolation of the active alkaloids was not until the 19th century. Geiger first prepared *l*-hyoscyamine in 1883 and Wohler prepared cocaine in 1862.

Figure 6 Common vinca and xanthine alkaloids.

A significant structural feature of the tropane alkaloids are that they are esters of an organic acid that is attached at the 3-position in either an α- or β-configuration to the central tropane structure. Very gentle neutral hydrolysis of these compounds produces tropine and the corresponding organic acid. In the case of *l*-hyoscyamine, the most widespread alkaloid of *Solanaceae* plants, the hydrolysis products are tropine and *s*-(−)-tropic acid. In the presence of more vigorous thermal and acidic conditions, tropine can undergo additional reactions to form a variety of products, and oxidation of tropine leads to both equatorial and axial N-oxide isomers. This is illustrated in Figure 5 for atropine.

A representative listing of some of the many methods published for the more common tropane alkaloids is presented in Table 6.[116–135]

2.6 Vinca Alkaloids

There are approximately 100 alkaloids that are present in six species of the genus *Vinca*. This group of plants are found throughout western Asia and the Mediterranean region of Europe. The most important species are *Vinca major* and *Vinca minor*, and the more common compounds include apovincamine, eburnamenine, hervine, reserpinine, sarpagine, (−)-tabersonine, vincadine, vincamajine, and vincamine. Of these, vincamine is the most important alkaloid and may be found at levels up to 2–3%. However, at least half of the vincamine currently used is partially synthesized from tabersonine, and numerous derivatives of vincamine have been prepared.[1]

A typical feature of the *Vinca* alkaloids is the eburna nucleus, which results in a characteristic mass spectrometric pattern. The major fragmentation pathway occurs via Diels–Alder reaction in the C-ring. The radicals produced can undergo two reaction schemes resulting in two major fragments with *m*/*z* differences of 41. For example, in the case of apovincamine, ions are observed at 308 and 267, and for eburnamenine, ions are observed at 249 and 208. However, besides the eburna nucleus, the remaining structural features vary widely between the different alkaloids, as illustrated by eburnamonine, vinblastine and vincamine in Figure 6.

This makes the prediction of chromatographic properties much more unlikely compared to alkaloids with more definable structural changes in terms of their effect on retention (e.g. the common opium alkaloids shown in Figure 3).

A representative listing of some of the methods published for the more common vinca alkaloids is presented in Table 7.[136–141]

2.7 Xanthine Alkaloids

The xanthine alkaloids are found throughout nature and the most common compounds in this group are caffeine, theophylline and theobromine. They share a number of pharmacological properties, including central nervous system, cardiac, respiratory stimulant, and smooth-muscle relaxant.

The central structural feature of the xanthine alkaloids is their purine nucleus (lower row of compounds in Figure 6). These three compounds are easily analyzed by a variety of methods, as summarized in Table 8, including many reversed-phase HPLC assays.[53,142–180]

2.8 Miscellaneous Alkaloids

There are a wide variety of other alkaloids that vary widely in terms of their source of origin, structure, and pharmacological activities. Because of space limitations it is not possible to consider each of these in a more in-depth discussion, but some of the more important are given in Figure 7 and methods for these as well as other alkaloids are given in Table 9.[181–223]

An antibiotic is a chemical substance, produced by microorganisms (or recently, synthetic routes) which has the capacity to inhibit the growth of other microorganisms/bacterial agents. The terminology for antibiotics stems from the Latin term of antibiosis *and the noun* antibiotic *was coined by Professor Waksman in 1942. Considered as a single therapeutic class, antibiotics are one of the most diverse groups of medicinal agents. They can be grouped into several subclasses depending on their source, structure and activity. These are the cephalosporins, penicillins, quinolones, streptomyces and tetracycline. In addition to these agents, the sulfonamides and other miscellaneous compounds are also included owing to their antibacterial activity.*

1 INTRODUCTION

Antibiotics include a broad spectrum of compounds that are diverse in structure as well as in their mode of action within an organism resulting from the many different sites where they may block or impede bacterial growth. Common mechanisms of action include the inhibition of cell wall synthesis (e.g. cephalosporin and penicillin), membrane function (e.g. gramicidins, nystatin, and streptomycin), ribonucleic acid metabolism (e.g. griseofulvin and neomycin), deoxyribonucleic acid metabolism (e.g. actinomycin and daunomycin), purine and pyrimidine synthesis (e.g. sparkomycin and tubercidin), protein synthesis (e.g. chloramphenicol, erythromycin, and tetracycline), respiration (e.g. antimycins and oligomycins), and oxidative phosphorylation (e.g. gramicidins and valionomycins). In some instances a given antibiotic may influence multiple sites. For example, streptomycin affects both membrane function and protein synthesis, while griseofulvin affects ribonucleic acid metabolism and deoxyribonucleic acid metabolism. Neomycin affects ribonucleic acid metabolism and protein synthesis. They are therapeutically used as antibacterial, antiinfective, antifungal, antiparisitic, antimicrobial and in some cases anticancer drugs. Certain antibiotics like the tetracyclines may have a broad spectrum of activities and inhibit the growth of a range of microorganisms including Gram-negative and positive bacteria, species of rickettsia and mycoplasma, certain protozoa and large viruses while other antibiotics like erythromycin and troleandomycin are more limited in scope.

Penicillins are the oldest recognized antibiotics originating from the pioneering work of Fleming. They have the 3,3-dimethyl-7-oxo-4-thia-1azabicyclo[3.2.0]heptane-2-carboxylic acid parent structure, I, shown below. The 6 position substitution is respectively a [(aminophenylacetyl)amino], [(phenylacetyl)amino], [[(2-propenylthio) acetyl]amino] or [(phenoxyacetyl)amino] group for the common drugs ampicillin and penicillin G, O, and V. Likewise, a close structurally related group of antibiotics are the cephalosporins, II.

(I)

(II)

Some of the more important pathogens where these antibiotics play a significant role in treatment of infections are *Actinomyces israeli*, *Bacillus anthracis*, *Clostridium perfringens*, *Corynebacterium diphtheriae*, *Diplococcus pneumoniae*, *Escherichia coli*, *Hemophilus influenzae*, *Proteus mirabilis*, *Shigella dysenteriae*, *Staphylococcus*

aureus, *Streptococcus hemolyticus*, and *Streptococcus viridans*.

Although most antibiotics are produced totally or in part via fermentation processes, compounds like chloramphenicol are manufactured synthetically. Examples of semisynthetic products are ampicillin, methicillin, oxacillin and phenethicillin. These are synthesized by chemically modifying the patient's natural product. In some instances, the initially identified semisynthetic compounds have been later found to be produced biosynthetically. Tetracycline is a good example of this type of compound which was initially synthesized via the catalytic dehalogenation of chlortetracycline but was later produced biosynthetically.

Antibiotics, as a major class of pharmaceuticals, have been assayed by a variety of procedures. In many instances these have involved either chromatographic or spectrophotometric methodology. In the latter, a variety of reagents have been used to form highly colored products. In terms of chromatographic procedures reversed-phase high-performance liquid chromatography (HPLC), and more recently capillary electrophoresis methodology, have become increasingly important. In some instances post-column colorimetric reactions have been used to facilitate detection.

The remainder of this article is divided into six major sections with a representative summary of more recent analytical methodology given in tabular form.

2 GENERAL INFORMATION

2.1 Cephalosporins

The cephalosporins are the second family of β-lactam antibiotics discovered after the penicillins and there are numerous parallelisms between the two families. However, unlike the penicillins, they are generally considered to be broad-spectrum antibiotics for both Gram-positive and Gram-negative pathogens. All of the cephalosporins are semisynthetic derivatives of the natural cephalosporin C antibiotic. Their general mode of action is via inhibiting bacterial wall synthesis similar to the penicillins. There is a marked variation for each cephalosporin against β-lactamase. The most resistant compound against this enzyme is cephalothin.

There are strong historical, biological and chemical similarities between the cephalosporins and the penicillins. The common feature is the β-lactam ring,

Table 1 Methodology for measuring common cephalosporins

Compound	Technique	Method/comments[a]
Cephalosporins (general)		Topics of a general nature that have been considered and are related to the analysis of this class of antibiotics include the separation of various compounds on polymeric ion-exchange resins,[1] comparison of chromatographic methods for purity evaluation of them,[2] measurement of the retention behavior of various cephalosporins,[3] and the use of 2-nitrophoenylhydrazine[4] and second-derivative spectra[5] for determining them.
Cefepime	Spectrometric	Diffuse reflectance mid-IR and X-ray diffraction methods have been developed for characterizing the dihydrate in the monohydrate cefepime · 2HCl drug substance. Excellent correlation was obtained between the two techniques with detection limits better than 1% for both.[6]
Cefaclor	Chromatographic	Two gradient elution HPLC methods useful for identifying impurities, degradation products and formulation excipients have been reported.[7,8] In the latter instance, both photodiode array and MS multidimensional detection approaches were used. HPLC microbore conditions have been used to separate the analyte, defazolin, deftizoxime and cefaloridine.[9] The effects of temperature and eluent composition on the capacity factors of the analyte and the related cephalosporins, cefonicid, cephazolin, cefodizime, cephaloridine, cefamandole, and cephalotin, have been studied.[10]
	Spectrometric	A stability-indicating colorimetric method has been reported where the analyte can be measured in the presence of its degradation products by heating it in an alkaline sorbitol–zinc ion solution for 10–25 min at 90 °C, followed by treatment of the resulting solution with 0.1 N sodium hydroxide to form the piperazine-2,5 derivative, and measurement of the absorbance at 334 nm.[11] Two colorimetric methods have been described that are based on either the oxidation of the target compound with sodium hypochlorite or its reaction with 1-chlorobenzotriazole. Both obey Beer's law and are applicable for dosage forms.[12] Likewise, cefaclor has been measured as its 1 : 1 Ni(II) complex which forms in weakly acidic media but hydrolyzes to a hydroxo complex under basic conditions.[13]

Table 1 (*continued*)

Compound	Technique	Method/comments[a]
Cefadroxil	Chromatographic	An isocratic ion-pairing HPLC method has been developed for assaying three cephalosporins (cefadroxil, cephalexin and cefaclor), and two anti-TB drugs (isoniazid and pyrazinamide). The separations are carried out on a C_{18} column using tetrabutylammonium hydrogensulfate (0.025 M) in combination with pH 3.0 methanol–acetonitrile–triethylamine.[14]
		The analyte has been assayed in capsules by reversed-phase HPLC that employs a C_{18} column, 90 : 10 water–acetonitrile adjusted to pH 3.5 with phosphoric acid as the eluent, *p*-hydroxyphenylacetamide as an internal standard and UV detection at 254 nm.[15] The detection limits for the procedure are 0.8 μg mL^{-1}.
		A comparative study between an HPLC method and a microbiological procedure has been reported. Recoveries were greater than 97% with coefficients of variation below 0.7%.[16] Similarly, multicenter trials have been carried out to evaluate an alternative chromatographic approach.[17]
		Eighteen different C_{18} stationary phases and copolymer columns have been evaluated by European Pharmacopoeia and USP HPLC protocols and a recommendation made that poly(styrene–divinylbenzene) columns be used for measuring the analyte.[18]
	Spectrometric	Tablets and capsules containing the analyte have been assayed by one of three approaches that involve treatment with (1) 3-methyl-2-benzothiazoline hydrazone, HCl and Ce(IV) in sulfuric acid, (2) 4-aminophenazone and potassium hexacyanoferrate or (3) 2,6-dichloro-quinone-4-chlorimide. The absorbance of the resulting colorimetric products are monitored at 410, 510 and 620 nm, respectively.[19] In addition, cefadroxil has been measured colorimetrically as its Cu(II) and V(V) complexes[20] and with ethylene blue[21] as well as using two of the procedures reported above for cefaclor.[11,12]
		In addition to the above colorimetric approaches, cefadroxil, and the related antibiotics cefamandol, cefoxitin, cefapirin and ceftriaxone, have been studied using circular dichroic spectroscopy.[22]
Cefixime	Chromatographic	A robotic procedure has been developed for evaluating the content uniformity of cefixime in oral dosage products.[23]
	Spectrometric	The analyte has been converted to the hydroxamic acid analog with 0.3 mL of methanolic 6.25% hydroxylamine hydrochloride–6.25% NaOH and subsequently to a colored 1 : 3 (metal-to-ligand) complex using methanolic 0.2% Fe(III) perchlorate–1.6% $HClO_4$. The absorbance of the resulting product, which obeys Beer's law from 80 to 320 μg mL^{-1}, is measured at 525 nm.[24]
Cefotaxime	Chromatographic	The analyte has been assayed in the presence of its dimer and major degradation products using CE. Results compare with those obtained under reversed-phase HPLC conditions.[25,26]
	Spectrometric	The analyte has been measured at 228.6 nm using its first-derivative UV spectrum. The procedure can be carried out in the presence of corresponding degradation products.[27] In addition, see the colorimetric procedure for cefixime above.[24]
Cefradine	Chromatographic	An isocratic HPLC method has been described for the analyte that uses a polystyrene–divinylbenzene column operated at 50 °C and an eluent of 14.5 : 10.5 : 75 acetonitrile: 0.02 M Na octanesulfonate: 0.2 M phosphoric acid: water.[28]
Ceftazidime	Chromatographic	A reversed-phase procedure has been developed for studying the storage stability of plastic syringes containing the analyte. The chromatographic separations are carried out on an Ultrasphere-ODS column and detection is at 254 nm.[29] Likewise, ceftazidime has been measured densitometrically following its thin-layer separation.[27]
	Spectrometric	The analyte has been measured at 268.6 nm using its first-derivative UV spectrum. The procedure can be carried out in the presence of corresponding degradation products.[27]
Ceftiofur	Chromatographic	High molecular weight impurities have been determined in ceftiofur using aqueous-based size-exclusion chromatography. Linear responses were observed from 0.005 to 9.25 μg of the impurities with detection limits of 0.03%.[30]

(*continued overleaf*)

Table 1 (*continued*)

Compound	Technique	Method/comments[a]
Ceftriaxone	Chromatographic	A high-performance thin-layer method has been introduced for measuring milligram quantities of the analyte. Recoveries and linearity are acceptable and agree with those obtained by the USP method.[31]
	Electrochemical	Ceftriaxone has been measured electrochemically using cathodic stripping voltammetry[32,33] and differential pulse polarography.[34] In the latter instance it can be determined in the presence of cefobid.
	Spectrometric	See the colorimetric procedure for cefixime above, which is also useful for assaying this analyte.[34]
Cefuroxime	Chromatographic	Cefuroxime has been determined in mixtures that also contain aminophylline and theophylline by reversed-phase LC. The method is capable of assaying as little as 7.5 μg mL^{-1} of the analyte in the presence of 16 and 13 μg mL^{-1} of the co-agents, respectively.[35]
	Spectrometric	The analyte has been measured at 306 nm using its first-derivative UV spectrum. The procedure can be carried out in the presence of corresponding degradation products.[27]
		Other spectrometric methodology that has appeared includes the use of near-IR reflectance[36] and spectrofluorimetric[37] spectroscopy for the quality control of the analyte in tablets. Likewise, a number of other related properties of the analyte may be found elsewhere.[38]
Cephalexin	Chromatographic	Cephalexin has been analyzed in capsules by a reversed-phase HPLC method that uses a C_{18} column, 90 : 10 water–acetonitrile adjusted to pH 3.5 with phosphoric acid as the eluent, *p*-hydroxyphenylacetamide as an internal standard and UV detection at 254 nm. The detection limits are 0.8 μg mL^{-1}.[15]
		The analyte also has been measured in tablets using a C_{18} column, 50 : 50, 0.1% orthophosphoric acid–methanol eluent adjusted to pH 7.5 with triethylamine, methyl paraben as the internal standard and UV detection at 254 nm.[39]
		An alternative HPLC approach has been suggested for measuring the content and stability of the analyte in commercial products.[40] A follow-up nine-laboratory comparative study has demonstrated that this method gives results that compare favorably with a commonly used microbiological method.[41]
	Electrochemical	The analyte has been assayed by first degrading it in alkaline media followed by adsorptive stripping voltammetry.[42] In addition to the quantitation aspects, this work also focuses on developing a better understanding of the mechanism of degradation and the electrode reaction processes.
	Spectrometric	A spectrophotometric procedure has been developed for the analyte and the results obtained using it have been found to compare favorably with those obtained by LC. Additionally, both cephalexin and its acid-induced degradation product are not affected by the presence of excipients.[43]
		Another method has been reported that is based on reacting cephalexin with acetylacetone–formaldehyde, which produces a yellow chromophore that is stable for up to 3 h. This approach is specific for β-lactam antibiotics.[44] Cephalexin also has been determined by alternative colorimetric procedures that involve its reaction with imidazole reagent[45] and with alkaline Co(III).[46]
Cephalothin	Chromatographic	A comparison of LC methods has been reported for the analyte[47] and it has been one of the compounds used as part of a general study that examines postcolumn chemiluminescence as a detection technique for β-lactam ring containing antibiotics in the LC.[48] A number of penicillins also are included.
Cepharadrine	Chromatographic	A multilaboratory comparison of a pharmacopeia bulk drug substance method has been carried out.[49]
	Spectrometric	Cepharadrine can be assayed by the colorimetric method for cefaclor discussed above, using a λ_{max} of 345 nm[11] and by an alternative procedure.[50]

[a] IR, infrared; CE, capillary electrophoresis; C_{18}, octadecyl-modified silica; UV, ultraviolet; USP, United States Pharmacopeia; MS, mass spectrometry; LC, liquid chromatography.

which is hydrolyzed by β-lactamase. These similarities are key to developing analytical methods for this class of drugs. In view of the chemical structure, it is not unusual that β-lactamase enzyme is capable of hydrolyzing the β-lactam ring of both the cephalosporins and penicillins. The carboxylic group is important to both families of compounds. Antibacterial activity and stability (penicillins vs cephalosporins) is defined by the stereospecificity and geometry of the fused side ring. Side chains and stereochemistry play an important role in determining their antibacterial activity.

A listing of the more common cephalosporins and related analytical methodology that has been developed for assaying them is summarized in Table 1.

2.2 Penicillins

The name penicillin was coined in 1929 by Professor Fleming. Penicillins comprise a large family of natural and semisynthetic agents fermented by *Penicillium* and other soil-inhabiting fungi. The penicillins are noted for bactericidal rather than simply bacteriostatic properties and are nontoxic. The unifying chemical structure among them is the central seven-membered thiazolidine–β-lactam ring system. The nucleus common to all penicillins is the fused thiazolidine–amino-β-lactam that consists of L-cysteine and D-valine. The free carboxyl group of the thiazolidine is essential for therapeutic effectiveness. In 1940 several researchers embarked on a scientific endeavor to identify and isolate this class of compounds and as the result of this important pioneering work the penicillins were instrumental during World War II for treating battle casualties.

Crystalline penicillin drug substance and formulated products are sufficiently pure and stable when stored at room temperature and in a dry state. However, all compounds/products deteriorate rapidly at elevated temperatures or when exposed to moisture. The fundamental course of degradation is hydrolysis of the β-lactam ring.

Table 2 Methodology for measuring penicillins

Compound	Technique	Method/comments[a]
Penicillins (general)		Several penicillins have been studied by mercurimetric titration with potentiometric end-point detection. The consecutive formation of reaction products during the titrations were monitored by reversed-phase LC and reaction schemes defined. In the case of benzylpenicillin, at the end of titration reaction, benzylpenicilloaldehyde and a 1 : 1 complex of mercury and penicillamine were present.(51) In addition the titrimetric determination of this group of antibiotics using 2-iodoxybenzoate has been considered.(52)
	Chromatographic	A reversed-phase HPLC method has been developed for the analyte that uses a C_{18} column, 35% methanol in 1 mM potassium hydrogenphosphate buffer as the eluent and postcolumn chemiluminescence for detection.(53) A mixture of seven penicillins have been separated on a C_8 column using gradient elution conditions. During this investigation a variety of flow programs were examined in order to obtain optimal performance in terms of minimal baseline drift and maximum response for the pulsed amperometric detector used.(54) Other general chromatographic reports include a study of the retention properties of monobasic penicillins under ion-pairing reversed-phase conditions,(55) an investigation of their separation on polymeric ion-exchange resins,(56) and an LC/electrochemical method for assaying a variety of compounds.(57)
	Electrochemical	The electrochemical oxidation of penicillins at a gold electrode in a flow injection analysis system also has been reported.(58)
	Spectrometric	General colorimetric procedures have been reported for penicillins that use Ellman's reagent(59) and 2-nitrophenylhydrazine.(60)
Aminopenicillinic acid	Chromatographic	See the general reversed-phase HPLC method above.(53)
Amoxycillin	Chromatographic	Amoxycillin has been assayed by a combined isocratic HPLC approach similar to USP method 23 and a gradient HPLC elution approach. Eleven laboratories took part in evaluating the methods and found that reproducibilities were better than 1.3% and that the isocratic approach was most useful for content control and the gradient approach was more suitable for purity control.(61) The analyte has been simultaneously measured with clavulanic acid using a β-cyclodextrin stationary phase, 65 : 35 pH 4.5 acetate buffer–methanol containing tetraethylammonium acetate as the eluent and detection at 225 nm.(62) A reversed-phase isocratic method has appeared for assaying the analyte in pharmaceutical formulations that also contain cloxacillin and it is capable of simultaneously detecting manufacturing precursors and acid hydrolysis decomposition products of both drugs. The separations are carried out on a C_{18} column using an 85 : 15 20 mM pH 2.0 phosphate buffer–acetonitrile eluent with 100 mM SDS eluent and UV detection at 230 nm.(63) Micellar electrokinetic capillary chromatography(64) and HPLC/MS(65) methods have been developed for evaluating the analyte and its potential impurities. In the first instance the separation is carried out at 15 kV and 25 °C using a 50 μM ID × 44 cm fused-silica capillary and 70 mM pH 6.0 sodium phosphate containing 125 mM SDS and 5% acetonitrile as the run buffer. Detection is at 230 nm.

(*continued overleaf*)

Table 2 (*continued*)

Compound	Technique	Method/comments[a]
	Spectrometric	The analyte has been determined colorimetrically after treating it with dehydroascorbic acid. The approach is specific for penicillins having amino acid side chains and is more accurate and precise than compendia methods.[66] Alternatively, the analyte has been measured at 390 nm following its reaction with acidic formaldehyde at 90 °C for 1 h. The method can be applied to a variety of dosage forms without interferences from excipients, coloring agents and flavor additives.[67] Likewise, acetylacetone–formaldehyde also has been used to assay the analyte in combination products without interference of cloxacillin and excipients.[68] Several other colorimetric methods have been reported for assaying the analyte. These are based on either oxidizing it with sodium hypochlorite or reacting it with 1-chlorobenzotriazole,[69] formation of a chloranil charge-transfer complex[70] and treatment with acenaphthenequinone.[71]
	Miscellaneous	Additional reversed-phase,[72–75] gel permeation,[76] micellar electrokinetic capillary,[77] electrochemical,[78,79] spectrometric,[80,81] and stopped-flow fluorimetric[82] methods may be found elsewhere.
Ampicillin	Chromatographic	An interlaboratory study evaluated several LC assay procedures and found that the USP method was the most selective and that cefradine was a better internal standard than caffeine.[83] However, in a second study involving seven sites, consistency across locations was not good.[84] A LC method has been published that uses luminol chemiluminescence detection to obtain enhanced sensitivity.[85] Additional HPLC conditions for this analyte also are available.[86]
	Electrochemical	Both direct current polarography and differential pulse polarography have been used to assay the analyte in pharmaceutical dosage forms. Prior to carrying out the electrochemical measurements, the analyte is converted to its nitroso derivative using nitrous acid. Linearity of the calibration curves is 8–200 and 2–160 $\mu g\,mL^{-1}$ respectively.[87] Alternative polarographic[88] and conductometric titration[89] methods also have been used to assay the analyte.
	Spectrometric	The analyte has been determined colorimetrically after treating it with dehydroascorbic acid. The approach is specific for penicillins having amino acid side chains and is more accurate and precise than compendia methods.[90] Alternatively, the analyte has been measured at 380 nm following its reaction with acidic formaldehyde at 90 °C for 1 h. The method can be applied to a variety of dosage forms without interferences from excipients, coloring agents and flavor additives.[91] The analyte also has been assayed colorimetrically after formation of a chloranil charge-transfer complex,[70] reaction with acetylacetone–formaldehyde to form a colored product that is measured at 400 nm and obeys Beer's law between 8 and 140 $\mu g\,mL^{-1}$[92] and treatment with other reagents such as dehydroascorbic acid[90] and nitrobenzene.[93] A second-derivative UV procedure has appeared for measuring the analyte and cloxacillin. The formulated product is dissolved in water and spectral readings are made between 260 and 300 nm. The derivative measurements for the two antibiotics are at 269 and 288 nm, respectively.[94] Alternatively, a hydrolysis method has been developed which is specific for ampicillin in the presence of cloxacillin.[95] The suitability of near-IR spectroscopy as an alternative to several compendial tests has been examined and has been found to be able to replace identification, water content and assay for release of ampicillin trihydrate bulk drug substance procedures.[96]
Azlocillin	Chromatographic	A stability-indicating reversed-phase HPLC method has been developed which is capable of resolving degradants formed when the analyte is stored at elevated temperatures.[97]
Benzylpenicillin	Chromatographic	A study has been carried out to examine seven isocratic reversed-phase methods for separating benzylpenicillin and related substances on C_{18} or C_8, phenyl and poly(styrene–divinylbenzene) columns. The manufacturer's method, which uses a C_8 column and 62 : 38 0.05 M pH 3.5 phosphate buffer–methanol as the eluent, gave the best selectivity whereas the selectivity on poly(styrene–divinylbenzene) was poorest.[98] In another study, isocratic reversed-phase HPLC was examined by seven laboratories with the recommendation that it should be combined with gradient elution conditions for purity control.[99] The analyte and related impurities have been assayed by micellar electrokinetic chromatography using a fused-silica capillary operated at 25 °C and 12 kV with pH 6.5 40 mM NaH_2PO_4–150 mM-SDS running buffer and detection at 225 nm.[100]

Table 2 (*continued*)

Compound	Technique	Method/comments[a]
	Electrochemical	Both direct current polarography and differential pulse polarography have been used to assay the analyte in pharmaceutical dosage forms. Prior to carrying out the electrochemical measurements, the analyte is converted to its nitroso derivative using nitrous acid. Linearity of the calibration curves are 8–200 and 2–160 μg mL^{-1}, respectively.(101)
	Spectrometric	A differential colorimetric method has been developed that is based on the initial hydrolysis of the analyte and its subsequent reaction with ferricyanide.(102) The procedure also can be used for ampicillin and benzathine penicillin.
		An indirect spectrophotometric assay has been introduced for formulations containing the analyte and cloxacillin that involves the acid hydrolysis of the analyte followed by the extraction of the products into carbon tetrachloride and measurements made at 520 nm.(103)
		The reaction of the analyte with potassium iodate in acidic media has been investigated and a mechanism proposed.(104)
Carbenicillin	Electrochemical	Both direct current polarography and differential pulse polarography have been used to assay the analyte in pharmaceutical dosage forms. Prior to carrying out the electrochemical measurements, the analyte is converted to its nitroso derivative using nitrous acid. Linearity of the calibration curves are 8–200 and 2–160 μg mL^{-1}, respectively.(101)
Clavulanic acid	Chromatographic	The analyte has been measured by the general reversed-phase(53) and amoxycillin(62) methods presented above.
	Electrochemical	A polarographic method has appeared that can be used to quantify the analyte in the presence of amoxicillin. Clavulanic acid is first hydrolyzed with sulfuric acid and then measured at −0.75 V vs SCE.(105)
	Spectrometric	A stopped-flow fluorimetric kinetic assay has been developed for the simultaneous determination of clavulanic acid and amoxycillin.(106) The method involves the acidic reaction of the analytes with Ce(IV) and detection at 365 nm.
		Near-IR reflectance spectroscopy has been used for the quality control of cream formulations. Samples are extracted with light petroleum after initially dissolving them in methanolic sodium hydroxide.(107)
Cephalothin	Chromatographic	See the general reversed-phase HPLC methodology presented above.(53)
Cloxacillin	Chromatographic	Results have appeared from a collaborative LC study for determining cloxacillin in bulk drug, capsules and injectables that had coefficients of variations of less than 1%.(108) Also see the reversed-phase procedures for amoxycillin above(63) and elsewhere.(109)
	Spectrometric	See the second-derivative(94) and hydrolysis(95) UV methods for ampicillin and spectrometric method for benzylpencillin(102) above.
		Thermospray MS has been used to investigate the solvent degradation of the analyte which has been found to undergo hydrolysis followed by decarboxylation when exposed to aqueous solutions containing either acetonitrile or propanol or esterification when stored in either methanol or ethanol.(110)
Dicloxacillin	Chromatographic	See the general reversed-phase HPLC method above(53) and those appearing elsewhere.(111,112) In the latter instance, the eight laboratories involved in the comparative study reported coefficients of variation for repeatability of less than 0.6% and a reproducibility of 2.6%.
Flucloxacillin	Chromatographic	See the HPLC method for cloxacillin above.(113)
Methicillin	Chromatographic	See the general reversed-phase HPLC method above.(53)
Nafcillin	Spectrometric	The fluorescence intensity of nafcillin at 336 nm has been studied as a function of temperature and it has been concluded that control is essential in making reliable measurements since the intensity fell 1.1% for every 1 °C increase.(113) The analyte has been determined in mixtures that contain methicillin by constant-wavelength synchronous fluorimetry in combination with a partial least-squares multivariate calibration.(114) Besides these methods, the solid state of the analyte in frozen aqueous solutions has been studied by low-temperature X-ray powder diffractometry.(115)
Oxacillin	Chromatographic	See the HPLC method for cloxacillin above.(109)
Penicillamine	Chromatographic	A chiral method has been reported for the analyte that involves its derivatization with *o*-phthalaldehyde and 2-mercaptoethanol followed by separation on a β-cyclodextrin column.(116)
	Electrochemical	A cathodic voltammetric method has been reported that can be used to measure D-penicillamine in the presence of *N*-acetylcysteine and Ni(II).(117)

(*continued overleaf*)

Table 2 (*continued*)

Compound	Technique	Method/comments[a]
	Spectrometric	Penicillamine has been determined after first degrading it to penicillaminic acid using hypobromite and subsequently treating the residual hypobromite with fluorescein and measuring the absorbance at 517 nm.[118]
		Three methods have been suggested for the determination of D-penicillamine in bulk and in capsules which involve oxidation with ferrocyanide and complexation of the iron with either bipyridyl or phenanthroline.[119] These approaches can be used to evaluate the target analyte in the presence of its degradation products and other penicillins.
Penicillin	Chromatographic	See the general reversed-phase HPLC methodology above.[53–57]
Penicillin	Spectrometric	Two flow-injection methods have been developed for the analyte and tiopronin that are based on the oxidation of these drugs by thallium(III) in hydrochloric acid medium and measurement of the thallium(I) formed fluorimetrically at 419 nm.[120] Additional flow-injection methods are available.[121]
		Other spectrometric-based methods that have been reported for the analyte include accounts related to the fabrication of optic chemical sensors[122,123] and derivative spectroscopy.[124,125]

[a] C_8, octyl-modified silica; SDS, sodium dodecyl sulfate; SCE, saturated calomel electrode; ID, inner diameter.

Table 3 Methodology for measuring common quinolones

Compound	Technique	Method/comments[a]
Quinolones (general)	Chromatographic	A study has been carried out to evaluate the capacity factor of 22 fluoroquinolones. Results from the work demonstrate a linear relationship between capacity factor and antibacterial activity.[126] In addition, the influence of pH on the reversed-phase separation of fluoroquinolones[127] has been investigated and HPTLC conditions useful for resolving a variety of fluoroquinolones have been published.[128]
Ciprofloxacin	Chromatographic	LC methods have been described that can be used to quantify ciprofloxacin in the presence of its photodegradation products[129] and also in combination with its ethylenediamine analog or fluoroquinolonic acid[130] and chlorofluoroaniline, dichlorofluoroacetophenone, cyclopropyl acrylate and quinolinic acid.[131] Likewise, a reversed-phase method has been developed for measuring the analyte in tablet formulations that uses a C_{18} column.[132]
		Alternative chromatographic approaches that have been used include a GC method for measuring the analyte and also norfloxacin, sarafloxacin and temafloxacin as their *N*-acyl derivatives[133] and a TLC procedure for evaluating the photodegradation of ciprofloxacin in aqueous solutions.[134]
	Electrochemical	A ciprofloxacin PVC-coated wire electrode has been fabricated that is based on a molecular dispersion of 4-quinolones with dioctyl phthalate as the polymerization solvent mediator. The electrode has a Nernstian response over the range 0.1–100 nM and has been used to measure the analyte in pharmaceuticals via a standard addition technique.[135]
		The polarographic behavior of ciprofloxacin has been studied as a function of pH and a value of 8.5 has been found to be best for carrying out measurements at reduction potentials of −1.44 and −1.64 V.[136]
	Spectrometric	The UV photodecomposition of the analyte in acidic ethanol has been studied by several techniques and the brown crystals that formed were identified to be 7-amino-1-cyclopropyl-6-fluoro-1,4-dihydro-4-oxo-3-quinolonecarboxylic acid. A reversed-phase HPLC method for evaluating the purity of the analyte also is included in the reported work.[137]
		A colorimetric procedure has been described that is based on extracting the yellowish-orange product obtained by the cerium(IV) oxidation of the drug in acidic medium and measuring its absorbance at 345 nm. The color of the organic layer is stable for 4 h.[138] In addition, the dissociation and complexation behavior of the analyte and those of enoxacin, norfloxacin and ofloxacin have been examined.[139]
		Likewise, ciprofloxacin, ofloxacin and norfloxacin have been measured at 370 nm following treatment with Fe(III) nitrate nonahydrate.[140] In addition, several other spectrophotometric methods have appeared for ciprofloxacin that use either methyl orange, bromothymol blue,[141] *p*-benzoquinone,[142] 3-methylbenzothiazolin-2-one with ceric ammonium sulfate[143] or iron[144,145] as colorimetric reagents. In the last instance measurements were carried out by flow injection analysis at a rate of 250 samples h^{-1} with a precision of <0.9%.
Enoxacin	Electrochemical	The voltammetric and polarographic behavior of the analyte has been studied at a mercury electrode and the reduction, which occurs at 1.052 V vs Ag/AgCl, has been found to be irreversible and to form an adsorptive product.[146] An alternative polarographic procedure also has been reported for enoxacin.[147]

Table 3 (*continued*)

Compound	Technique	Method/comments[a]
	Spectrometric	The analytical methodology for ciprofloxacin discussed above[129] can be used to assay enoxacin.
Enrofloxacin	Chromatographic	Enrofloxacin has been quantified in tablets using a C_{18} column, 70 : 30 acetonitrile–water containing 0.1% triethylamine adjusted to pH 4 as the eluent and detection at 282 nm.[148]
	Spectrometric	The analyte also has been measured colorimetrically using either Folin–Ciocalteau reagent or Fe(III).[149]
Flumequine	Electrochemical	Tablets containing the analyte have been assayed polarographically using Britton–Robinson buffer containing methanol as the solubilizer. Well defined cathodic waves are obtained in the pH range 5–10.[150]
	Spectrometric	Flumequine also has been determined spectrophotometrically by direct chelation with iron(III) and treatment of the analyte with iron(III) hydroxamate followed by chelation with iron(III).[151]
Lomefloxacin	Chromatographic	An HPTLC method has been reported for the analyte that uses silica gel plates in combination with 18 : 2 : 1 methanol–water–ammonia as the development solvent. Scanning is carried out at 286 nm using afloxacin as an internal standard.[152]
	Spectrometric	Lomefloxacin has been determined in ground tablets by the formation of colored complexes using acidic solutions of either bromothymol blue, bromophenol blue, bromocresol purple or bromocresol green. The colorimetric measurements of chloroform extracts of the resulting complexes are made respectively at 416, 416, 422 and 412 nm.[152] Likewise, similar methodology also has been reported for measuring lomefloxacin and ofloxacin in another account[153] and it has been assayed with Folin–Ciocalteau reagent.[154]
Norfloxacin	Chromatographic	Both reversed-phase HPLC[155,156] and TLC[157] methods have been reported for measuring the analyte in combination with tinidazole.
	Electrochemical	A variety of electrochemical methods has been reported for norfloxacin that include DC and differential pulse polarography,[158] differential pulse stripping voltammetry,[159] and oscillopolarographic titrimetry.[160]
	Spectrophotometric	Tablets and eye drops containing the analyte have been assayed via initially treating them with 0.1 N H_2SO_4, filtering, mixing with ammonium sulfamate and ceric ammonium sulfate and extracting the yellow chromogen into chloroform. Measurements are made at 350 nm.[161] An alternative colorimetric method has appeared for studying the dissolution of the analyte that is based on its reaction with acidic Fe(III).[162] In addition to these procedures, other spectrometric methods can be found elsewhere;[163–166] also see the spectrometric methodology for ciprofloxacin above.[139,140]
Ofloxacin	Spectrometric	See the colorimetric[140] and related methodology[139] for ciprofloxacin and lomefloxacin above.[153] Other spectrometric methods[167] have been developed for ofloxacin, including an NMR assay.[168]
	Electrochemical	Assays have been reported based on adsorptive stripping,[169] potentiometric,[170] and related electrochemical[171] measurements.
Pefloxacin	Spectrometric	A direct UV method has been described for assaying tablets and composites that involves dilution of an equivalent amount of the powdered material in 0.1 N NaOH and measuring the resulting spectrum from 250 to 290 nm. An orthogonal polynomial function method is used to eliminate irrelevant absorption due to excipients.[172] Alternative UV and spectrofluorimetric procedures have been reported which involve an initial extraction of the tables with methanol and readings made under acidic conditions.[173] The analyte also has been determined colorimetrically following its treatment with iron(III).[174]
Rufloxacin	Chromatographic	The analyte has been examined using a reverse-phase HPLC procedure.[175]
	Spectrometric	A simple and rapid fourth-derivative UV method has been developed for rufloxacin hydrochloride and its main impurity in laboratory mixtures, bulk materials and pharmaceutical forms.[176] Likewise, a fluorimetric assay has been developed for measuring the analyte in pharmaceutical formulations.[177]
Temafloxacin	Chromatographic	HPLC procedures have been reported for determining minor impurities in temafloxacin hydrochloride[178] and for assaying the analyte in bulk drug and dosage forms.[179] In the latter instance, the procedure can be used for difloxacin and sarafloxacin.
	Spectrometric	A fluorimetric assay has been described for the determination of temafloxacin in pharmaceutical formulations. The samples are diluted with 0.1 M sulfuric acid and measured at 460 nm using an excitation wavelength of 276 nm.[180]

[a] HPTLC, high-performance thin-layer chromatography; GC, gas chromatography; TLC, thin-layer chromatography; PVC, poly(vinyl chloride); NMR, nuclear magnetic resonance.

This decomposition is catalyzed by penicillinase and various metals.

A listing of some of the more common penicillins and related analytical methodology that has been developed for assaying them is summarized in Table 2. In many cases HPLC, UV, colorimetric and microbiological approaches are commonly used.

2.3 Quinolones

The quinolones are a newer class of antibiotics and work on them continues to expand. The first compound discovered in the class was nalidixic acid and subsequently other related compounds have been synthesized based upon in vitro results and structure–activity relationships. The quinolones inhibit DNA synthesis in bacterial cells but not in mammalian cells of DNA topoisomerase. Likewise, the quinolones have a diverse ability to extinguish the micro-bioactivity of microbes.

The number of published methods for this class of compounds continues to increase. Although chromatographic and spectroscopic based methods tend to dominate, the compounds are also electrochemically active. A listing of some of the more common quinolones and related

Table 4 Methodology for measuring streptomycins and related analogs

Compound	Technique	Method/comments[a]
Abamectin	Chromatographic	A postcolumn normal-phase HPLC method has appeared for abamectin. Following the separation the analyte is reacted with naphthalene-2-sulfonic acid in an alkaline nonaqueous mixing solvent and the absorbance monitored at 570 nm.[181]
Amikacin	Chromatographic	The analyte has been assayed in the 2–100 $\mu g\,mL^{-1}$ range with relative standard deviations of 0.3–4.2% using a C_{18} column following its derivatization with *o*-phthalaldehyde. The effluent absorbance is monitored at 340 nm.[182]
	Electrochemical	A nonspecific conductometric procedure has been developed to monitor the strength of pediatric injectable dextrose solutions that contain amikacin, netilmicin, and tobramycin prepared by a centralized pharmacy service. The major limitation of the approach is that it cannot be applied to solutions that contain sodium chloride.[183]
		Thirteen aminoglycoside antibiotics have been determined by capillary zone electrophoresis using cetyltrimethylammonium bromide and indirect UV detection.[184]
Bekanamycin	Chromatographic	Bekanamycin and other related aminoglycoside antibiotics, including gentamicin, tobramycin, lincomycin, neomycin, kanamycin, and ribostamycin, have been measured in pharmaceutical preparations by CE in combination with EC. In the study both copper wall-jet electrodes and copper ion-capillary electrodes were evaluated and the latter were found to provide superior stability and reproducibility.[185]
Bleomycin	Chromatographic	A rapid reversed-phase method has been reported for measuring bleomycins in commercial products which uses sodium perchlorate as an ion-pairing reagent.[186]
		The luminescence of bleomycins in combination with Tb(III) has been studied and Tb(III) luminescence detection has been found to be compatible with a wide range of HPLC eluents.[187]
Clarithromycin	Chromatographic	An HPLC method has been developed that can resolve 15 nonpolar related compounds and process impurities that elute after *N*-demethyl-*N*-formyl-6-*O*-methylerythromycin A in clarithromycin bulk drug. All of the nonpolar compounds can be detected at the 0.02% (w/w) level.[188]
		Several other HPLC methods have been reported for clarithromycin.[189–191] In one of these, EC was done using a dual electrode which provided a detection limit of 100 pg[188] and in another case postcolumn reaction with ruthenium(III) and subsequent luminescence detection produced a calibration graph that was linear over four orders of magnitude.[191]
		HPLC with EC also has been used to study clarithromycin residues on various surfaces. After cleaning, any residual clarithromycin remaining can be removed from the surface by a wet swab–dry swab technique.[192]
Clindamycin	Spectrometric	Clindamycin has been determined spectrophotometrically as its ion-pair complex with Rose Bengal in a slightly basic medium. The colored product that forms at pH 7.5 is measured at 555 nm. Likewise, the analyte has been assayed by direct conductometric titration using Rose Bengal in a 2 : 1 ethanol–water mixture.[193]
		Alternative spectrometric and titrimetric methods also have been described for clindamycin. In the first case, the analyte is reacted with potassium iodate in an acidic medium, the liberated iodine extracted with cyclohexane, and the resulting solution measured at 520 nm. In the second method a direct titration of the drug is carried out with *N*-bromosuccinimide.[194]
Dirithromycin	Chromatographic	An HPLC method has been reported for dirithromycin that uses a C_{18} column, an eluent consisting of 44 : 19 : 37 acetonitrile–methanol–50 mM pH 7.5 potassium phosphate buffer, and UV detection at 205 nm.[195]

Table 4 (*continued*)

Compound	Technique	Method/comments[a]
Erythromycin	Chromatographic	The analyte has been separated under isocratic conditions using a C_{18} column and an acetonitrile–pH 6.5 phosphate buffer eluent containing tetrabutylammonium sulfate. The impurities most frequently observed in commercial samples were the propionate ester of erythromycin C and the amide, *N*-propionyl-*N*-demethylerythromycin A.[196]
		A multicenter study involving six laboratories and seven columns has been carried out and a method has been recommended for the analyte that uses a wide-pore poly(styrene–divinylbenzene) stationary phase.[197]
		An alternative study has been carried out that examines several C_{18} columns for their use in separating erythromycin and a gradient elution method has been developed for separating the analyte from seven possible impurities. The method is stated to be simpler, more rugged, faster, and more sensitive than a competing chromatographic procedure that uses a poly(styrene–divinylbenzene) stationary phase and it yields results similar to those obtained by microbiological procedures.[198]
		In addition to the above methodology, a host of other HPLC-based procedures have appeared for erythromycin. Examples of these may be found elsewhere.[199–203]
		The analyte also has been assayed by CE using a 50 mM pH 7.5 phosphate run buffer and an applied voltage of 20 kV. Likewise, 35% ethanol incorporated into a modified 150 mM pH 7.5 phosphate run buffer and an applied voltage of 30 kV have been used to facilitate the separation of erythromycin from erythromycin C, anhydroerythromycin, and *N*-demethylerythromycin A.[204]
	Spectrometric	Erythromycin and related macrolide antibiotics such as oleandomycin, spiromycin, and tylosin have been measured in fermentation broths after treatment with Fe(III). The product that forms in acetic acid–sulfuric acid is measured at 592 nm.[205] Additional colorimetric procedures have been reported that use bromothymol blue, methylthymol blue, and thymol blue as reagents.[206]
		Erythromycin has been determined spectrofluorimetrically via formation of an ion pair with erythrosine B and measuring the chloroform extract at 560 nm using an excitation wavelength of 544 nm. The method can be adapted to an unsegmented flow-injection system and used to assay the analyte in formulations.[207]
Gentamycin	Chromatographic	Injectable solutions containing gentamicin sulfate have been assayed by CE and direct UV detection using a borate buffer.[208] Likewise, the analyte has been analyzed using the CE/EC method for bekanamycin above[185] and by LC thermospray MS.[209] In the latter instance a simplex algorithm was used to optimize the separation.
Gramicidin	Chromatographic	Formulations containing the analyte have been evaluated by a reversed-phase procedure that involves an initial dilution step with aqueous 35% THF, a subsequent separation at 65 °C using an 8 mm PLRP-S column and 38 : 62 THF–water as the eluent and detection at 222 nm.[210]
Kanamycin	Chromatographic	A reversed-phase LC method has appeared for resolving kanamycin sulfate from kanamycins B, C, and D and from other impurities. The procedure involves a two-step gradient separation on a poly(styrene–divinylbenzene) column using aqueous eluents of 20 or 60 g L^{-1} sodium sulfate, 1.3 g L^{-1} sodium octanesulfonate and 50 mL/10.2 M pH 3.0 phosphate buffer and pulsed EC on a gold electrode following the postcolumn addition of sodium hydroxide.[211] The analyte also has been assayed by the CE/EC method described above for bekanamycin[212] as well as by flow injection methodology reported elsewhere.[212] In the latter case, the procedure is linear from 0.1 pM to 10 μM and common excipients do not interfere.
Lincomycin	Chromatographic	Samples containing the analyte have been analyzed after diluting them appropriately with 0.1 M NaOH and separating the resulting solutions on an 80-cm capillary using 0.1 M NaOH as the electrophoretic medium, an applied voltage of 26 kV and wall-jet amperometric detection at +0.675 V vs Ag/AgCl. Using this approach, lincomycin and lincomycin B can be separated within 15 min with a resolution of 2.3.[213] Lincomycins also have been measured by the CE/EC procedure for bekanamycin discussed above[185] as well as procedures appearing elsewhere.[214]
Moenomycin	Chromatographic	An HPTLC procedure has been developed for evaluating the purity of moenomycin A, B and C isolated from the fermentation broth of *Streptomyces bambergiensis.* Separations are carried out on silica gel high-performance plates activated at 110 °C for 30 min and developed using 13 : 7 1-propanol–25% aqueous ammonia. Subsequently, the plates are visualized by treatment with 1 : 2 acetic acid–chlorosulfonic acid, heating them at 100 °C for 5–7 min and scanning in reflectance mode at 550 nm.[215]

(*continued overleaf*)

Table 4 (*continued*)

Compound	Technique	Method/comments[a]
Neomycin	Chromatographic	A reversed-phase procedure has been reported for neomycin sulfate that uses a poly(styrene–divinylbenzene) copolymer column, a 0.2 M pH 3 phosphate buffer containing 70 g L^{-1} sodium sulfate and 1.4 g L^{-1} sodium 1-octanesulfonate as the eluent, and pulsed EC.[216] The relative amounts of the B and C components of neomycin sulfate have been evaluated using silica gel TLC plates, 15 : 85 methanol–20% aqueous sodium chloride, and fluorescence detection after derivatization with 4-chloro-7-nitrobenzo-2-oxa-1,3-diazole.[217] Likewise, an alternative HPTLC method has been described for neomycin A, B, and C that uses a development solvent of 35 : 20 : 20 : 5 methanol–25% aqueous ammonia–acetone–chloroform, and detection with fluorescamine.[218] The analyte also has been assayed by the CE/EC procedure for bekanamycin discussed above.[185]
	Spectrometric	An alternative procedure to the standard agar diffusion method for neomycin has been developed that uses triphenyltetrazolium chloride.[219] Likewise, the analyte has been measured indirectly by atomic absorption spectroscopy following its metal complexation.[220]
Nybomycin	Chromatographic	A combination of TLC, HPLC, and MS methods have been used to study nybomycin isolated from fermentation broths.[221]
Paromomycin	Chromatographic	Similarly, a variety of methods have been used to assay paromomycin sulfate including NMR spectroscopy, elemental analysis, ion chromatography, GC and LC.[222] In the last case, the separation was performed on a C_8 column using 0.2 M Na_2SO_4–1.2 mM sodium 1-heptanesulfonate–0.1% acetic acid as the eluent and fluorescence detection following postcolumn derivatization with *o*-phthalaldehyde and 2-mercaptoethanol. Additionally, LC/MS was performed on a C_{18} column with 2 : 3 methanol–0.7% aqueous heptafluorobutyric acid as the eluent.[222]
Ribostamycin	Chromatographic	Ribostamycin has been assayed by the CE/EC procedure for bekanamycin discussed above.[185]
Rifamycin	Spectrometric	A first-derivative method has been reported for the simultaneous determination of rifamycin SV sodium in injection solutions that also contain lidocaine. Readings are made at 312.0 and 254.6 nm.[223]
Roxithromycin	Chromatographic	Roxithromycin has been measured in tablets by HPLC. The reversed-phase separations are carried out using a C_{18} column, 35 : 65 methanol–0.067 M pH 4.0 phosphate buffer as the eluent, and UV detection at 210 nm.[224]
Streptomycin	Chromatographic	The analysis of streptomycin and 11 related aminoglycoside antibiotics has been carried out by CE utilizing borate complexation and direct UV detection. Quantification of dihydrostreptomycin and streptomycin was accomplished using 160 mM sodium tetraborate decahydrate and the determination of the purity of bulk dihydrostreptomycin was possible by the addition of the cationic surfactant, myristyltrimethylammonium bromide. Other compounds studied included amikacin, bekanamycin, kanamycin A, and tobramycin.[225] In addition, alternative GC[226] and TLC[227] procedures have appeared for the analyte.
	Electrochemical	The analyte and related compounds have been measured at ruthenium dioxide-modified graphite electrodes via an electrocatalytic process.[228]
	Spectrometric	Streptomycin and five other aminoglycoside antibiotics, neomycin, gentamicin, tobramycin, amikacin and kanamycin, have been measured fluorimetrically following their reaction with Eu(III) and monitoring the intensity ratio $R = I_{592\,nm}/I_{616\,nm}$, for free and bound europium ions, which is related to the concentration of the aminoglycoside. The results obtained by this procedure compare favorably with those obtained by a fluorimetric method that uses fluorescamine reagent.[229] In addition, the analyte and relate antibiotics have been assayed colorimetrically using cyanoacetamide.[230]
Spectinomycin	Chromatographic	An isocratic HPLC assay has appeared for spectinomycin dihydrochloride pentahydrate that is based on cation-exchange chromatography on a Dionex IonPac CS3 column at ambient temperature using 150 mM pH 6.0 sodium acetate. The method, which employs pulsed-amperometric detection, is suitable for the analysis of the drug substance.[231]
Tobramycin	Chromatographic	A rapid and sensitive LC method has been developed to quantify the release of tobramycin from polymeric drug delivery systems in vitro. Precolumn derivatization of tobramycin and the internal standard, kanamycin B sulfate, are carried out with 2,4,6-trinitrobenzenesulfonic acid and the products are separated under reversed-phase conditions using a C_8 column.[232] In addition, the CE/EC methodology for bekanamycin discussed above can be used to assay tobramycin.[185]
	Spectrometric	See the spectrometric methodology for streptomycin discussed above[229] and alternative procedures appearing elsewhere.[233]
Tylosin	Chromatographic	See literature.[234–236]
	Spectrometric	See literature.[237]

[a] EC, electrochemical detection.

Table 5 Methodology for measuring common sulfonamides and other miscellaneous antibiotics

Compound	Technique	Method/comments[a]
Sulfonamides (general)	Chromatographic	The reversed-phase behavior of seven common sulfonamides on a C_{18} column using acetonitrile–phosphate buffer as the eluent have been investigated. A number of different conditions, including buffer concentration, type and concentration of positively and negatively charged pairing reagents, column temperature and the ionic state of the solutes have been evaluated and the optimal eluent suggested for each compound.(238)
		Systematic studies have been carried out to characterize the general migration properties of many common sulfonamides under various electrophoretic conditions.(239–241) Similarly, HPTLC has been used to evaluate several sulfonamides.(242)
		A general procedure has been developed for assaying several common sulfonamides in pharmaceutical preparations that involves their initial derivatization to form the corresponding *N*-(1-naphthyl)ethylenediamine dihydrochloride azo dyes and subsequent reversed-phase micellar separation using a pH 7 0.05 M SDS eluent containing 2.4% pentanol.(243)
	Spectrometric	The colorimetric reagent *p*-benzoquinone has been used to measure a variety of sulfonamides in bulk and in dosage forms.(244) Likewise, photochemically induced fluorescence has been found to be a useful approach,(245) as has FTIR spectroscopy.(246)
Salazosulfapyridine	Electrochemical	The voltammetric properties of salazosulfapyridine have been studied by several polarographic procedures at both mercury dropping and static drop electrodes at various pHs. The analyte, which is reduced to a hydrazine derivative, can be determined by scanning differential pulse voltammetry and adsorptive stripping voltammetry in tablet formulations with relative standard deviations of 5% or better and detection limits in the range 0.2–0.5 ng mL^{-1}.(247)
Sulfadimetoxal	Electrochemical	The voltammetric behavior of the analyte has been studied by square-wave techniques and two methods have been developed for measuring it in aqueous samples and formulations.(248)
Sulfadimidine	Electrochemical	The analyte can be measured after reacting it with either salcylaldehyde or cinnamaldehyde. The optimal performance is reached in 30 min at 50 °C.(249)
	Spectrometric	Flow injection analysis methods based on fluorimetric or photochemically induced fluorescence have been developed for the analyte and also for sulfanilimide, sulfaguanidine and sulfacetamide.(250)
Sulfadiazine	Chromatographic	Reversed-phase conditions in combination with EC have been used to assay the analyte and also sulfamerazine and phthalylsulfathiazole. The calibration curves are rectilinear for all three drugs over the range 10–90 μM.(251) Likewise, the analyte has been assayed using an alternative HPLC method.(252)
	Spectrometric	The analyte has been determined colorimetrically by reacting it with dimethylamino-cinnamaldehyde and measuring the absorbance of the red chromogen that forms at 545 nm. The method is linear over the range 0.4–4.8 μg mL^{-1}.(253)
		A continuous-flow diazotization approach has been used for determining the analyte in dosage forms and for measuring its dissolution rates. An advantage is that it eliminates the frequent preparation of in situ generated nitrate solutions.(254)
		Samples containing the analyte are assayed by diluting them with methanol, irradiating the solution with a mercury lamp for 2.5 min, and reading the resulting photochemically induced fluorescence at 353 nm. The method is linear over the concentration range 0.1–4.1 μg mL^{-1}.(255) A similar procedure also can be used to measure sulfamethazine in the presence of sulfamerazine or sulfadiazine.(256)
		The analyte has been measured in the presence of nonsulfonamide antibiotics using a spectrophotometric partial least-squares multivariate method.(257) The same approach can be applied to sulfamerazine, sulfamethazine, sulfaquinoxaline and sulfathiazole.(258) In addition, the analyte has been determined by direct absorbance monitoring.(259)
Sulfaguanidine	Chromatographic	See the HPLC method for sulfadiazine above.(252)
Sulfamerazine	Chromatographic	See the HPLC method for sulfadiazine above.(252)
	Electrochemical	An electrochemical study of the oxidation of sulfamerazine has been carried out at a glassy carbon electrode and based on this an HPLC assay for the analyte, sulfadiazine and phthalylsulfathiazole has been developed.(251)
	Spectrometric	See the spectrometric method for sulfadiazine above.(258)
Sulfamethazine	Spectrometric	The influence of solvents on the photochemical induced fluorescence of the analyte has been examined. Detection limits of 80, 40 and 70 ng mL^{-1} were achievable when methanol, ethanol and 2-propanol were used, respectively.(260) Also see the fluorimetric method for sulfadiazine above.(256)

(*continued overleaf*)

Table 5 (*continued*)

Compound	Technique	Method/comments[a]
Sulfamethizole	Spectrometric	The analyte has been assayed in tablets using its ratio derivative spectrum[261] and after its reaction with *p*-benzoquinone.[244]
Sulfameth-oxazole	Chromatographic	The analyte and trimethoprim have been isolated from a formulation using a supercritical fluid extraction approach.[262] Both direct extraction of the aqueous-based samples and indirect extraction of the formulation from Celite have been evaluated.
	Electrochemical	The voltammetric properties of the analyte have been studied by several polarographic procedures at both mercury dropping and static drop electrodes and its reduction which takes place with difficulty is by a radical mechanism. For additional information, see salazosulfapyridine above.[247]
	Spectrometric	The analyte can be assayed in various formulations by either first-derivative or classical least-squares analysis of the UV methanolic spectra. In the first approach, the absorbance is measured at the zero-crossing wavelength, 288 nm, and in the second the spectrum is recorded from 200 to 350 to 200 nm.[263] The analyte also has been assayed using its ratio derivative spectrum[264] and fluorimetrically as its 1 : 1 β-cyclodextrin inclusion complex.[265]
Sulfametrole	Spectrometric	The analyte has been determined using its first-derivative spectrum.[266]
Sulfanilamide	Spectrometric	The analyte has been determined in binary mixtures that also contain sulfathiazole using the third- and fourth-order derivative spectra.[267] This method can be applied to other sulfanilamides.
Sulfathiazole	Chromatographic	See the HPLC method for sulfadiazine above.[252]
	Spectrometric	Sulfathiazole has been measured using its ratio derivative spectrum[267] and by a first-derivative solid-phase spectrophotometric approach.[268]
Tinidazole	Electrochemical	The analyte can be determined by a polarographic procedure with a well-defined sigmoid-shaped curve with an $E_{1/2}$ of −0.44 V vs SCE using a pH 5.5 Britton–Robinson buffer.[269]
	Spectrometric	The analyte has been assayed in combination with clotrimazole or norfloxacin using a derivative zero crossing point technique. Tablet extracts are prepared in 0.01 M NaOH and readings made between 220 and 300 nm.[270]
Chloram-phenicol	Chromatographic	LC/thermospray MS has been used to measure the analyte and three related compounds.[271]
	Electrochemical	The redox behavior of chloramphenicol under different pH conditions has been studied using a graphite electrode and parallel incident spectroelectrochemistry. Different reaction products have been found to be produced depending on pH.[272]
		The analyte in eye drops containing it were measured in 0.1 M NaOH solution using an Ni/C modified working electrode; a sensitive reductive wave of chloramphenicol was obtained by linear sweep voltammetry. The peak potential was −0.80 V (SCE). The reduction process was quasi-reversible.[273]
		A chloramphenicol sensor has been fabricated that is based on the displacement of an analyte–dye conjugate from a molecularly imprinted polymer. The sensor is immune to interference from analyte-related derivatives and is linear from 3 to 1000 $\mu g\,mL^{-1}$.[274]
Clotrimazole	Spectrometric	The analyte has been determined in combination with tinidazole using a derivative zero crossing point technique. Tablet extracts are prepared in 0.01 M NaOH and readings made between 220 and 300 nm.[270]
Isoniazid	Chromatographic	An isocratic ion-pairing HPLC method has been developed for assaying three cephalosporins (cefadroxil, cephalexin and cefaclor) and two anti-TB drugs (isoniazid and pyrazinamide). The separations are carried on a C_{18} column using tetrabutylammonium hydrogensulfate (0.025 M) in combination with pH 3.0 methanol–acetonitrile–triethylamine.[14]
	Spectrometric	The analyte has been measured colorimetrically after treatment with host of reagents such as azoic diazo component 36,[275] 2,3,5-triphenyltetrazolium chloride,[276] Fe(III) phenanthroline,[277] ethyl-8-quinolinoxy acetate[278] and radiochloramine-B.[279]
Trimethoprim	Chromatographic	Trimethoprim has been measured simultaneously with nitrofuranotion using a micro C_{18} column, a pH 6 water–acetonitrile eluent containing triethylamine and UV detection at 270 nm.[280] Likewise, an alternative HPLC approach has been used to evaluate the analyte in the presence of its degradation products.[281]
	Electrochemical	The voltammetric properties of the analyte have been studied by several polarographic procedures at both mercury dropping and static drop electrodes and its reduction is by either a two- or four-electron process (depending on the acidity) that leads to the di- or tetrahydropyrimidine derivative as a final product. For additional information, see salazosulfapyridine above.[247]

Table 5 (*continued*)

Compound	Technique	Method/comments[a]
	Spectrometric	The analyte has been assayed in various formulations by either first-derivative or classical least-squares analysis of the UV methanolic spectra. In the first approach, the absorbance is measured at the zero-crossing wavelengths, 240 nm, and in the second the spectrum is recorded from 200 to 350 nm.[263] Other first-derivative,[266] ratio-derivative[264] and linear absorbance[282] methods also have been reported. The analyte can be measured in formulations containing sulfamethoxazole via oxidizing it with alkaline persulfate. The stable reaction product is formed after heating for 30 min and it is measured at 355 nm. Beer's law is obeyed in the concentration range $10-60\,\mu g\,mL^{-1}$.[283]

[a] FTIR, Fourier transform infrared.

Table 6 Methodology for measuring common tetracyclines

Compound	Technique	Method/comments
Tetracyclines (general)	Chromatographic	Commercial formulations have been extracted and the analytes separated on a C_{18} column using 84 : 16 0.05 M pH 2.5 phosphate buffer–acetonitrile as the eluent and measured amperometrically at 1.2 V using a glassy carbon electrode. This approach has been demonstrated to be useful for the simultaneous determination of trace amounts of chlortetracycline, demeclocycline, doxycycline, methacycline, minocycline, oxytetracycline and tetracycline and also for the separation of their common impurities (epi, anhydro and epianhydro contaminants).[284] A systematic study of capillary electrophoretic operating conditions has been carried out and optimized methods for the analysis of various tetracyclines have been reported. Different buffer systems are suggested for the separation of tetracycline, oxytetracycline and demeclocycline from their respective major impurities, including the 2-acetyl-2-decarboxamido derivatives. The nonionic surfactant Triton X-100 and methyl-β-cyclodextrin were found to be useful in obtaining improved selectivity in the case of oxytetracycline and demeclocycline.[285] Additional capillary electrophoretic methodology may be found elsewhere[286,287] The micellar electrokinetic migration behavior of six tetracyclines has been investigated in the pH range 5.0–9.0 using ammonium acetate buffers containing SDS. In addition, several other surfactants also were studied. Complete separation of the analytes were achieved in 8 min on a fused-silica capillary using a 15 mM ammonium acetate buffer containing 20 mM SDS at 15 kV. The use of this procedure to obtain information about octanol–water partition coefficients is also discussed.[288]
	Spectrometric	A flow injection assay has been developed that uses aminophenazone and $Fe(CN)_6$ as reagents and it has been used to assay doxycycline, oxytetracycline, rolitetracycline and tetracycline with relative standard deviations <1% for samples in the $10-100\,\mu g\,mL^{-1}$ range.[289]
	Miscellaneous	Other topics of a general nature that have been reported include the analysis of various tetracyclines using simplex optimized flow injection analysis,[290] the use of micellar solutions to enhance the luminescence,[291] the europium-sensitized luminescence of tetracyclines[292] and the loss of tetracyclines via their adsorption on laboratory glassware.[293]
Chlortetracycline	Chromatographic	A study has been carried out involving five laboratories and six different columns to demonstrate that the proposed HPLC method could be used to determine the analyte and also major related substances such as demeclocycline and 4-epichlortetracycline.[294] In two additional cross-laboratory studies, both poly(styrene–divinylbenzene) stationary phases[295] and C_{18} phases[296] were found to be useful for assaying the analyte with variations among the different laboratories between 1 and 2%. Similarly, the usefulness of polymeric stationary phases for separating the analyte and four related substances has been demonstrated in another study.[297] Other analytical methodologies that have been reported for chlortetracycline are a TLC purity method that has been found to be comparable to LC approaches,[298] an HPLC procedure for resolving the keto–enol tautomers of the analyte and 4-epi-chlortetracycline in combination with UV and NMR spectroscopy to elucidate their structures.[299]

(*continued overleaf*)

Table 6 (*continued*)

Compound	Technique	Method/comments
	Spectrometric	The analyte has been measured by solid-surface room temperature phosphorescence[300] and by chemiluminescence.[301,302] In the latter instance, a flow injection approach was employed based on the reaction of the chlortetracycline with $KMnO_4$ in acidic medium in the presence of a micellar agent. It is linear from 1 to 1000 $\mu g\,mL^{-1}$ and has a detection limit of 0.60 $\mu g\,mL^{-1}$ for the analyte and 0.40 $\mu g\,mL^{-1}$ for tetracycline.
Demeclocycline	Chromatographic	This analyte has been examined by HPLC,[303] TLC (see the method for chlortetracycline)[298] and CE.[304] In the last approach doxycycline is detectable at the 0.3% level and measurable at 0.4% in the presence of its degradation products.
	Spectroscopic	The analyte has been determined colorimetrically with sodium molybdate.[305]
Doxycycline	Chromatographic	A CE method has been developed for doxycycline that is capable of measuring it in the presence of possible impurities.[306] Likewise, the TLC fluorimetric methodology discussed above for chlortetracycline can be used to evaluate the purity of the analyte.[298]
	Spectrometric	See the methodology for chlortetracycline above.[300]
Metacycline	Chromatographic	Assays for metacycline have been introduced that use TLC in combination with UV/fluorescence densitometric detection to evaluate its purity.[298,307]
	Spectrometric	See the methodology for chlortetracycline above.[300]
Minocycline	Chromatographic	Both capillary zone electrophoresis[308] and HPLC have been used to measure minocycline.[309,310] In the latter case, acidic eluents in combination with poly(styrene–divinylbenzene) columns are used to resolve minocycline and seven other tetracycline derivatives.
	Electrochemical	The voltammetric behavior of the analyte at a water–nitrobenzene interface has been investigated by normal, semi-differential and semi-integral cyclic voltammetry. Resulting from the work was the development of a semi-differential cyclic voltammetric procedure for measuring the analyte in the range 5–200 $\mu g\,mL^{-1}$ with results comparable to those obtained by the USP method.[311]
Oxytetracycline	Chromatographic	Oxytetracycline has been separated from related impurities and degradation products as its magnesium complex under nonaqueous capillary electrophoretic conditions. The method has been used to assay ointments with high selectivity and good precision.[312] In addition, other CE approaches have been reported for the analyte.[287,313,314] Results from a comparison study of past HPLC methods for the analyte have indicated that the use of polymeric stationary phases gives the most promising results.[315] Likewise, TLC methodology has been reported for oxytetracycline and doxycycline that is useful for evaluating their purity.[316] The separations are carried out on silica gel thin-layer plates using 59 : 35 : 6 dichloromethane–methanol–water with 10% sodium acetate solution adjusted to pH 9.0 as the development solvent.
	Spectrometric	The analyte has been assayed by first extracting it into cyclohexane and then determining it by direct UV measurements in combination with orthogonal polynomial coefficient corrections to minimize interference from excipients.[317] Other spectrometric procedures described for oxytetracycline include one based on its reaction with sodium molybdate,[318] a flow injection approach that uses a carrier stream of iron(III),[319] and its reaction with hydrogen peroxide catalyzed by copper ion to form a chemiluminescent product.[301]
Tetracycline	Chromatographic	The ruggedness of the USP HPLC method for tetracycline has been evaluated. A statistical analysis of column aging and its effect on the separation performance suggests that a C_8 column is to be preferred over a C_{18} column.[320,321] Capillary electrophoretic assays have been developed for measuring the analyte in the presence of its degradation impurities that are based on conventional aqueous[322] and nonaqueous[323] approaches. Also see the electrophoretic general methodology above.[287] Several comparative studies have been carried out for methods related to tetracycline including one where four laboratories evaluated seven different columns for suitability,[324] another where a TLC method for the analyte was compared with an HPLC method[325] and a final study involving capillary electrophoretic methodology.[326] Other related TLC[327] and HPLC[328] methods appear elsewhere.
	Spectrometric	See the methods for chlortetracycline above.[301,302] In the latter method the limit of detection for the analyte is 0.40 $\mu g\,mL^{-1}$. In addition to these continuous flow procedures, other spectrometric methods,[329,330] as well as a postcolumn time-resolved luminescence method for HPLC may be found elsewhere.[331]

analytical methodology that has been reported for them is summarized in Table 3.

2.4 Streptomycin and Related Analogs

The compounds that fall within this category were originally synthesized as organic bases by appropriate strains of actinomycete (*Streptomyces griseus*). The first drug isolated from actinomycetes was streptomycin in 1943. Other compounds have loosely been included in this category because they also were biosynthesized via similar microbial routes.

Streptomycin itself is strongly basic with an empirical formula of $C_{21}H_{39}N_7O_{12}$. It and related compounds are stable when dry and they retain full potency at room temperature. However, the presence of moisture will affect their stability. Solutions are normally stable at room temperature in the pH range 3–7 and optimal solution stability is typically between pH 6 and 7. Exposure to light may darken solutions and impact purity.

Analytical methodology that has been developed for assaying streptomycin and its related analogs is summarized in Table 4.

2.5 Sulfonamides and Miscellaneous Antibacterial Agents

Summarized in Table 5 are representative analytical procedures that are useful for assaying a number of the more common sulfonamides and also miscellaneous compounds that possess antibacterial activity. In addition to the wide variety of chromatographic and spectrometric methodology that has appeared, a number of electrochemical assays have been published for this grouping of compounds and various studies have been carried out to characterize their electrochemical behavior.

2.6 Tetracyclines

The tetracyclines comprise a family of both biosynthetic and semisynthetic derivatives that are characterized by an unusual antimicrobial background. They are therapeutically used against both Gram-positive and Gram-negative bacteria and various viruses. However, these compounds (Table 6) are not active against the common cold or fungi. The first tetracycline (7-chlorotetracycline) was discovered in 1948 and it was the second compound to be developed after chloramphenicol as a broad-based antibiotic. Four other tetracyclines were developed from natural sources (duomycin, oxytetracycline, demeclocyclin and tetracycline). Subsequently, rolitetracycline, methacycline, doxycycline and minocycline were produced as semisynthetic derivatives.

All of the tetracyclines have a common skeleton (i.e. an octahydro analog of naphthacene) but differ in their substituents, which has a significant influence on their individual solubilities. The tetracyclines are amphoteric and can be manufactured as both acidic and basic salts. Differences are observed in their stability at elevated temperatures in both acidic and alkaline media, which can have a significant impact on the bioavailability of an individual compound when administered orally. In the dry state both the free compound and its corresponding salts are stable at room temperature when protected from light and moisture. In solution, the compounds undergo both acid and basic hydrolysis (ring cleavage) but the degree of cleavage is dependent upon the particular drug. Bulk drug substance and drug product should be placed in opaque light-protecting bottles and, if optimal stability is desired, a desiccant added to the container.

Summarized in Table 6 are representative procedures that have been developed to assay the tetracyclines. In general, this methodology parallels trends noted above for the other antibiotics.

ABBREVIATIONS AND ACRONYMS

C_8	Octyl-modified Silica
C_{18}	Octadecyl-modified Silica
CE	Capillary Electrophoresis
EC	Electrochemical Detection
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
HPLC	High-performance Liquid Chromatography
HPTLC	High-performance Thin-layer Chromatography
ID	Inner Diameter
IR	Infrared
LC	Liquid Chromatography
MS	Mass Spectrometry
NMR	Nuclear Magnetic Resonance
PVC	Poly(vinyl chloride)
SCE	Saturated Calomel Electrode
SDS	Sodium Dodecyl Sulfate
TLC	Thin-layer Chromatography
USP	United States Pharmacopeia
UV	Ultraviolet

This article describes both pre- and postcolumn derivatization chemistry used in conjunction with either chromatography or capillary electrophoresis (CE) to facilitate the determination of drugs. Generally, only prederivatization is used in gas chromatography (GC), principally to enhance the volatility, temperature stability, and/or detectability. The GC section considers derivatization of drugs by reagent class: alkylation, acylation, and silylation. The GC sample-handling section describes an approach that combines the extraction and derivatization steps together. Both pre- and postcolumn derivatization are common approaches for high-performance liquid chromatography (HPLC) and many of these methods have been adapted for CE. Derivatization for HPLC is often directed toward aliphatic amines, carboxylic acids, or alcohols that are difficult to detect at low levels by absorbance, luminescence, or electrochemical means. In addition, small hydrophilic molecules upon prederivatization are often converted into larger more hydrophobic compounds, making reversed-phase HPLC easier or even feasible. The HPLC section considers derivatization of drugs based on the following types: alkaloids, amines, antibiotics, barbiturates, carbonyl compounds and carboxylic acids, catecholamines, hydroxy compounds, steroids, and sulfur compounds. For the GC and HPLC sections, tables are included, giving the structures of the more important derivatizing agents, the analytes, and the corresponding reaction products. A brief rationale for derivatization chemistry with CE concludes this article. For CE, derivatization is often done to improve detectability as the path length for absorbance detection is very short and fluorescence can be effective using laser-based systems.

1 INTRODUCTION

Derivatization in conjunction with chromatography or CE can be done either in an off-line mode, often prior to the separation step (prederivatization), or in an on-line mode (postcolumn derivatization). Generally, only prederivatization is used in GC, principally to enhance the volatility, temperature stability, and/or detectability. Both pre- and postcolumn derivatization are common approaches for HPLC and many of these methods have been adapted for CE. Derivatization for HPLC is often directed toward aliphatic amines, carboxylic acids, or alcohols that are difficult to detect at low levels by absorbance, luminescence, or electrochemical means. In addition, small hydrophilic molecules upon prederivatization are often converted into larger more hydrophobic compounds, making reversed-phase HPLC easier or feasible. For CE, derivatization is often done to improve detectability as the path length for absorbance

detection is very short and fluorescence can be effective using laser-based systems.

The desirable conditions to be met for precolumn derivatization are (i) the reaction stoichiometry and product structure should be known, (ii) the reaction should be reasonably fast and should proceed quantitatively (or at least reproducibly), and (iii) the derivative should be stable, readily separable, and distinguishable from the starting material. One advantage of the prederivatization approach is that simple equipment is commercially available to allow for the reaction chemistry to be done in the batch mode. Subsequent sample analysis using an autoinjector and a standard unmodified chromatograph is straightforward. Alternatively, the use of a robot to carry out the entire prederivatization chemistry and an HPLC instrument equipped with an autosampler means that the sample throughput will usually be limited by the chromatographic step.

Because postcolumn derivatization involves mixing the column effluent with a reagent or passing it through a reactor to form the derivative before it is detected, the automation step is built in. Sample handling before analysis is minimal, reducing the chance of error from sample loss. The conditions desirable to be met for postcolumn derivatization are (i) although the reaction must be rapid, within about 2 min, and be reproducible, the reaction products do not have to be very stable, (ii) the reagent itself must have no, or a very low, detection response, and (iii) the reactor volume must be small to minimize dilution and band broadening.

The remainder of the article is divided into three major sections: GC, HPLC, and CE. The GC section considers derivatization of drugs by reagent class: alkylation, acylation, and silylation. In addition, a short discussion on sample handling is included. The HPLC section considers the derivatization of drugs based on the following types: alkaloids, amines, antibiotics, barbiturates, carbonyl compounds and carboxylic acids, catecholamines, hydroxy compounds, steroids, and sulfur compounds. A brief rationale for derivatization chemistry with CE concludes this article.

2 GAS CHROMATOGRAPHY

Prior to analysis by GC, compounds containing functional groups with active hydrogens such as COOH, OH, NH, and SH need to be protected. Compounds with these functional groups tend to form intermolecular hydrogen bonds, reducing volatility. They are also thermally unstable and can interact with either fused silica or the stationary phase, causing peak broadening. Several good review sources describing derivatization reagents, reactions, and applications for GC are available. At least one commercial company provides a good overview of the commercial reagents and the apparatus available.[1] Two other references are fairly comprehensive in describing many of the published methods for GC derivatization either by reaction class[2] or by the type of organic compound.[3] A recent overview describing gas chromatography/mass spectrometry (GC/MS) methods for drugs of abuse contains prederivatization protocols.[4] Alkylation, acylation, and silylation reaction chemistries are the most common approaches to derivatization for GC and are the primary focus in this article. A specific example and an overview for each of these reaction classes are described below.

2.1 Alkylation

Alkylation represents the replacement of an active hydrogen, found in an organic acid or amine, by an aliphatic or aliphatic–aromatic (e.g. benzyl) group. Alkylation reactions can also be used to prepare ethers from alcohols such as phenol, thioethers from sulfur compounds, and *N*-alkylamines, amides, and sulfonamides from amines. One principal chromatographic use is the conversion of carboxylic acids into esters that are stable and volatile with good chromatographic characteristics. Esterification of carboxylic acids has traditionally been done through reaction with an alcohol in the presence of an acid catalyst. Generally, a 1–2-mg sample of the acid is heated with 100 μL of the alcohol (methanol or ethanol) containing 3-M HCl for 30 min at 70 °C. The alcohol is evaporated, leaving the ester as a residue. A faster reaction in only about 2 min using a boiling water-bath is possible with a BF_3–methanol solution (Table 1, reagent 1). Often the esters are extracted into *n*-heptane followed by evaporation of the solvent.[5] *N*,*N*-Dimethylformamide dimethylacetal (DMFDA) is a rapid methylating agent, which provides quantitative yields upon mixing in a nonaqueous solvent with the sample of interest (Table 1, reagent 2). Carboxylic acids are converted to methyl esters, thiols to thioethers, and phenols to methyl ethers. Primary amines are converted into their *N*,*N*-dimethylaminoethylene derivatives and amino acids are simultaneously modified as this derivative at the amino group and as the methyl ester at the carboxyl group. Aliphatic hydroxyl groups are not methylated. Ethyl, propyl, *n*-butyl, and *t*-butyl acetals may be used analogously.

Alternatively methylation of active functional groups can be done using methyl iodide (CH_3I) or diazomethane ($CH_2{=}N^+{=}N^-$). Sixteen diuretics such as amiloride and hydrochorothiazide were extracted from urine and then reacted with methyl iodide at 70 °C for 2 h to form methyl derivatives. Short columns and high flow rates permitted analysis times by GC/MS of less than 4 min.[6] Carbamazepine, diclofenac, and ibuprofen were methylated

Table 1 Common GC derivatives – alkylation

Number.	Reagent[a]	Compounds	Derivatives
1	 (BF_3–methanol)	R–COOH	$R-COOCH_3$
2	 (DMFDA)	R–COOH $R-NH_2$ R–OH R–SH	$R-COOCH_3$ $R-NH-(CH_2)_2-N(CH_3)_2$ $R-O-CH_3$ $R-S-CH_3$
3	 (PFB-Br)	R–COOH R–OH Sulfonamides R–SH	 R–O–(PFB)  R–S–(PFB)
4	 (TMAH)	R–OH $R-NH_2$ R–COOH	$R-O-CH_3$ $R-NH-CH_3$ $R-COOCH_3$

[a] DMFDA, *N*,*N*-dimethylformamide dimethylacetal; PFB-Br, pentafluorobenzyl bromide; TMAH, trimethylanilinium hydroxide.

using diazomethane and determined by GC/MS down to 10 ng L^{-1}, while sulfamethoxazole and its metabolites were determined by liquid chromatography/mass spectrometry (LC/MS).[7]

Pyrolysis of a quaternary ammonium salt (QUAT) in the presence of the organic analyte can be a convenient methylation procedure.[8] Upon injection of the QUAT mixed with the drug having a reactive amino, hydroxyl, or carboxyl group into the hot injection port (250–300 °C), the appropriate methyl derivative is formed (Table 1, reagent 4). The derivative is swept onto the analytical column for separation and detection. Trimethylanilinium hydroxide (TMAH) is generally the commercially recommended reagent, but trimethyl (α,α,α-trifluoro-*m*-tolyl)ammonium hydroxide can be used at a lower injection temperature, which is important for labile unsaturated fatty acids. This method is particularly good for barbiturates, sedatives, xanthine bases, phenolic alkaloids, and dilantin. Pharmaceuticals such as clofibric acid, ibuprofen, carbamazepine, naproxen, ketoprofen, and diclofenac were identified and quantitated by GC/MS via on-line derivatization using tetrabutylammonium salts with large volume (10 μL) sample injection.[9]

Pentafluorobenzyl bromide (PFB-Br) can convert carboxylic acids, phenols, sulfonamides, and thiols into halogenated derivatives that can be easily detected by electron capture (EC) (Table 1, reagent 3). For carboxylic acids, the reaction is run in an organic solvent in the presence of a base such as a tertiary amine for 5 min at 40 °C. The determination of cannabidiol (CBD) and the internal standard tetrahydrocannabidiol in blood plasma involved first derivatization by refluxing a hexane extract with PFB-Br overnight with stirring followed by purification on a Florisil™ column using hexane.[10] A typical EC chromatogram obtained on a packed 5% OV-225 glass column is shown in Figure 1. Although a packed column has limited separation capability, it can handle larger amounts of sample. In addition, because the hexane fraction was evaporated to dryness and reconstituted in a small hexane volume, a detection limit of 50 ng mL^{-1} of CBD in plasma was possible. A second reported example is the solid-phase extraction (SPE) of 19 pharmaceuticals from samples such as sewage, surface, ground, and drinking water. Prederivatization of these pharmaceuticals with PFB-Br before GC/MS was slightly more effective than silylation chemistry (explained in Section 3.3).[11] Detection limits down to 1 ng mL^{-1} were possible. Alternatively, tertiary amines have been derivatized with pentafluorobenzyl chloroformate prior to GC with EC detection.[12]

Alkylchloroformates have been utilized for the derivatization of amphetamines, often before solid-phase microextraction (SPME) and GC/MS. Amphetamine and methamphetamine in urine were immobilized on

Figure 1 Typical chromatogram from a plasma sample containing 2.0 μg of the internal standard tetrahydrocannabidiol (1) and calculated to contain 1.5 μg of the CBD (2). (Reproduced with permission from Ref. 10.)

an Extrelut extraction column as free bases and then derivatized to *N*-propoxycarbonyl derivatives with propyl chloroformate [$CH_3(CH_2)_2(C{=}O)OCl$].[13] A follow-up study by the same authors used SPME to concentrate the same *N*-propoxycarbonyl derivatives from the vial headspace before GC.[14] Calibration curves were linear from 0.5 to 50 mg L^{-1}. A similar approach was used for amphetamine and ephedrine drugs using 2,2,2-trichloroethyl chloroformate to convert the compounds to the corresponding carbamates before GC/MS determination using electron impact and chemical ionization approaches.[15] Plasma, urine, and hair samples were analyzed and detection limits were from 2 to 5 ng mL^{-1} for the biological liquids and in the 0.1–0.2 ng mg^{-1} range for hair. After conversion of amphetamines to their free base using triethylamine, an SPME fiber coated with an alkylchloroformate was used to sample the headspace and cause derivatization.[16] More conventionally, alkylchloroformate derivatization of cocaine and two derivatives was done before SPME and GC/MS analysis.[17] Detection limits in human hair of 0.1–0.5 ng mg^{-1} were similar to those reported in reference 16.

Ethyl chloroformate activated (*R*)(+)-l-phenylethylamidation of *R* and *S* naproxen and desmethylnaproxen enantiomers before GC separation within 11 min on a 5% phenyl–95% methylsiloxane stationary phase.[18] Using the chiral derivatizing agent (*S*)(−)*N*-trifluoroacetyl-L-prolyl chloride (L-TPC) to modify the amine group, resolution at 2.0 of enantiomeric amphetamines was possible with good linearity by GC/MS to 45 ng mL^{-1}.[19]

2.2 Acylation

Acylation is the conversion of carboxylic acids, thiols, or amines (compounds that have active OH, SH, and/or NH moities) into esters, thioesters, and amides, respectively. Acyl derivatives, even geometric isomers, tend to undergo mass spectrometry (MS) fragmentation that leads to useful structural information and differentiation. Perfluoroacylimidazoles such as trifluoroacetylimidazole (TFAI), pentafluoropropionylimidazole (PFAI), or heptafluorobutylimidazole (HFBI) can react with hydroxyl groups and primary or secondary amines to generate the halogenated derivative and the relatively inert by-product imidazole (Table 2, reagent 1). Generally, the reaction times are 1–3 h at 75 °C. Indoleamines and indole alcohols, which are acid-sensitive compounds, have been modified by this procedure. Metoclopromide, an antispasmodic agent related to procainamide, has been derivatized with HFBI for GC with EC detection.[20] These reagents are often used in bifunctional derivatization schemes involving silylation chemistry. For example, phenolic amines can be silylated with *N*-trimethylsilylimidazole (TMSI) to protect the hydroxyl group and acylated to protect the amine group. Other halogenated imidazoles such as *p*-bromobenzyl- and *p*-chlorobenzylimidazole have been used because the detectability of the derivatives can be enhanced using EC. However, the volatility and stability of the derivatives under GC conditions tend to be lower compared to the fluorinated types.

N-Methylbistrifluoroacetamide (MBTFA), shown in Table 2 as reagent 3, permits trifluoroacetylation of primary or secondary amines and carbohydrates under mild nonacidic conditions.[21] For carbohydrates, a single derivative for mono-, di-, tri-, and tetrasaccharides was obtained. The *N*-methyltrifluoroacetamide by-product is stable and volatile, being compatible with GC. After extraction with *t*-butyl methyl ether and SPE, amphetamines have been derivatized with MBTFA and separated on a 5% phenylmethylsilicone column.[22] On-line flash injection of extracted amphetamines with MBTFA provided GC/MS separation and identification of 12 compounds at limits of detection of 2.5–6.9 ng mL^{-1}.[23]

Perfluoro acid anhydrides [R′(C=O)–O(C=O)R′], such as trifluoro-, pentafluoro-, and heptafluoro-acid anhydride (TFAA, trifluoroacetic anhydride; PFAA, pentafluoropropionic anhydride; HFAA, heptafluorobutyric anhydride) react readily with alcohols, phenols, and urine for the preparation of perfluoroacyl derivatives, which are particularly useful for EC detection (Table 2, reagent 2). Triethylamine is added, as part of the reaction mixture, to neutralize the acidic by-products and drive the reaction to completion. Drugs of abuse are often derivatized in this way before GC/MS confirmation.

Table 2 Common GC derivatives – acylation

Reagent[a]	Compounds	Derivatives
	R–OH			$R' = CF_3$(TFAI), C_2F_5(PFAI), or C_3F_7(HFBI)	$R–NH_2$				R–OH 	$R' = CF_3$(TFAA), C_2F_5(PFAA), or C_3F_7(HFAA)		 (MBTFA)	$R–NH_2$ R–OH R–SH	
[a] TFAI, trifluoroacetylimidazole; PFAI, pentafluoropropionylimidazole; HFBI, heptafluorobutylimidazole; TFAA, trifluoroacetic anhydride; PFAA, pentafluoropropionic anhydride; HFAA, heptafluorobutyric anhydride; MBTFA, *N*-methylbistrifluoroacetamide.

A GC/MS example of derivatization of amphetamine and methamphetamine by HFAA[24] is shown in Figure 2(a) and (b). The splitting of the peaks is due to the presence of deuterated internal standards. Excess HFAA, which causes a high background level, column contamination, and eventual degradation of the stationary phase, was removed by the procedure outlined below. The drugs of interest were extracted from 2 mL of urine by SPE columns with a 10% 2-propanol in a chloroform elution solvent. Sodium periodate oxidation of interfering drugs was carried out if necessary. The extract was acidified with 10% HCl in methanol before evaporation and reconstitution of the residue in hexane with 0.1-M trimethylamine. HFAA was added and the mixture was heated in a sealed tube for 1 h at 70 °C. After cooling, deionized water was added to the tube, the tube shaken, and the aqueous phase discarded. A 4% ammonia solution was shaken with the remaining hexane volume and then the organic layer removed for injection into the GC/MS system. The limit of quantification and limit of detection were both on the order of 50 ng mL^{-1} and the linearity was observed up to at least 4000 ng mL^{-1}. Newer, but similar, approaches using HFAA for the derivatization of amphetamines and derivatives in biological samples use novel sample preparation methods. Examples of such methods are mixed mode reversed phase-ion exchange SPE[25,26] prior to derivatization, SPME with derivatization using a polydimethylsiloxane fiber,[27] and extraction with toluene containing HFAA.[28]

An important application of PFAA and HFAA derivatization involves the MS differentiation of substituted methamphetamine[29] or phenethylamine[30] isomers from the controlled drug 3,4-methylenedioxymethamphetamine (3,4-MDMA or Ecstasy). Without derivatization, the MS spectra for these GC-separated isomers are virtually identical to that of 3,4-MDMA. Acylation of the NH or NH_2 functional group present in all these compounds with either PFAA or HFAA lowers the basicity of the amine, which allows other fragmentation pathways to occur, resulting in clear distinguishing MS spectra.

Figure 2 (a) Total ion current chromatogram of HFAA-derivatized amphetamine (1) and methamphetamine (2). The overloaded peak at about 5.6 min is due to excess HFAA. (b) Total ion current chromatogram of HFAA-derivatized amphetamine (1) and methamphetamine (2) after extraction of the excess derivatizing agent. The baseline level in this chromatogram is only about 10% of that in (a). The splitting of the drug peaks in both chromatograms is due to the presence of the deuterated internal standards (amphetamine-d_5 and methamphetamine-d_8). (Reproduced with permission from Ref. 24.)

Comparable approaches using TFAA for derivatization of phenylalkylamines such as methamphetamine[31] and others including phenteramine, cathinone, and mescaline[32] or ketamines[33] and subsequent GC/MS have been reported. Human metabolism of ephedrines including ephedrine and phenylpropanolamine was generally found to be low based on TFAA derivatization and GC/MS results.[34] Piperazine drugs and their metabolites were separated by LC/MS after SPE and forensic confirmation was made by GC/MS of their TFAA derivatives.[35]

The use of nonfluorinated anhydrides is less common. After derivatization with acetic anhydride in the presence of $KHCO_3$, six serotonin uptake inhibitors such as venlafaxine and fluvoxamine were extracted with a polydimethylsiloxane-divinyl benzene microextraction fiber for 30 min before GC/MS determination.[36] Amphetamines, using 2% acetic anhydride, were converted to primary and secondary amides upon injection of the sample solution and furan was used as the reagent for chemical ionization MS to improve selectivity.[37]

2.3 Silylation

Silylation is the most widely used derivatization scheme for GC. Active hydrogens from acid, alcohol, thiol, amine, and amide groups can all be protected, usually with trimethylsilyl (TMS) groups. The ease of silylation of these functional groups can be ordered: alcohol > phenol > carboxylic acid > amine > amide. Steric hindrance is also a factor within a class of organic compounds. For alcohols, the reactivity order is primary > secondary > tertiary, and, for amines, primary > secondary. Trimethylchlorosilane (TMCS) is the simplest reagent that can be used, often to derivatize carboxylic acids (Table 3, reagent 1). TMCS is often used in conjunction with hexamethyldisilazane (HMDS) (Table 3, reagent 2) to improve the silylation of sugars and related compounds. In general, silylation reagents are unstable and must be protected from moisture. Because an excess of the silylating agent is used in the derivatization reaction to minimize the problem of moisture or other acidic components in the sample, it is recommended that the excess silylation reagent be evaporated using a stream of nitrogen before injection of the sample into the GC column. This avoids several problems such as large reagent blank peaks in the chromatogram and fouling of the flame ionization detector by SiO_2 deposits. A polar stationary phase such as poly(ethylene glycol) (Carbowax™ 20 M) or free fatty acid phase is derivatized by excess silylation reagent and cannot be used.

Silylacetamides are represented in the most popular group of silylation agents, owing to their ability to react quickly and quantitatively under mild conditions. *N*,*O*-Bis(trimethylsilyl)acetamide (BSA) is a highly reactive TMS donor (Table 3, reagent 3). *N*,*O*-Bis(trimethylsilyl)trifluoroacetamide (BSTFA) (Table 3, reagent 4) has the advantage of giving a more fluorinated by-product than BSA. This permits derivatization of lower molecular weight analytes without potential overlap of the trifluoroacetamide by-product.

Cannabinol derivatives were volatilized using the BSTFA reaction and then microextracted from the headspace before GC/MS.[38] Limit of detection values ranged from 0.01 to 0.02 ng mg^{-1}. The addition of TMCS to BSTFA promotes the derivatization of amides, secondary amines, and hindered hydroxyl groups. A comprehensive article on drug detection methodology describes the determination of cocaine, heroin, and metabolites in hair, plasma, saliva, and urine samples after isolation by SPE and subsequent derivatization with

Table 3 Common GC derivatives – silylation

Number.	Reagent[a]	Compounds	Derivatives
1	 (TMCS)	R–COOH	
2	 (HMDS)	R–OH	R–O–Si(CH$_3$)$_3$ 3	 (BSA)	R–OH R–NH$_2$	R–O–Si(CH$_3$)$_3$ 								R–COOH	4	 (BSTFA)	Same as BSA, leaving group  more volatile than that of BSA	
5	 (MSTFA)	Same as BSA, leaving group  is very volatile	
6	 (TMSI)	R–OH (steroids) R–COOH	R–O–Si(CH$_3$)$_3$ 		No reaction with amines	

[a] TMCS, trimethylchlorosilane; HMDS, hexamethyldisilazane; BSA, *N*,*O*-bis(trimethylsilyl)acetamide; BSTFA, *N*,*O*-bis (trimethylsilyl)trifluoroacetamide; MSTFA, *N*-methyl-*N*-trimethylsilyltrifluoroacetamide; TMSI, *N*-trimethylsilylimidazole.

BSTFA with TMCS before analysis by GC/MS.[39] After spiking the plasma, saliva, and hair extracts with internal standards, they were passed through SPE columns and the drugs eluted with a methylene chloride-2 propanol-ammonia solvent. The eluent was evaporated to dryness, reconstituted with acetonitrile, and allowed to react with a BSTFA/TMCS mixture at 60 °C for 30 min before analysis by GC/MS. Representative chromatograms are shown in Figure 3(a–c). Separations were affected on a relatively short 12 m × 0.2 mm i.d. capillary column. The limit of detection for the analyte was about 1 ng mL^{-1} in urine, saliva, and plasma and 0.1 ng mg^{-1} in hair. A BSTFA/TMCS mixture was also shown to be effective for derivatization of the opioid analgesic

Figure 3 Single ion monitoring recordings of extracts from (a) standard cocaine/opiate hair, (b) drug-free control hair, and (c) a hair sample collected from a heroin user. Analytes are identified as follows: anhydroecgonine methyl ester (1), [^{2}H-3]ecgonine methyl ester (2), ecgonine methyl ester (3), ecgonine ethyl ester (4), [^{2}H-3]cocaine (5), cocaine (6), [^{2}H-3]cocaethylene (7), cocaethylene (8), [^{1}H-3]benzoylecgonine (9), benzoylecgonine (10), norcocaine (11), norcocaethylene (12), benzoylnorecgonine (13), [^{2}H-3]codeine (14), codeine (15), [^{2}H-3]morphine (16), morphine (17), norcodeine (18), [^{2}H-6]-6-acetylmorphine (19), [^{2}H-3]-6-acetylmorphine (20), 6-acetylmorphine (21), normorphine (22), [^{2}H-9]heroin (23), heroin (24). (Reproduced with permission from Ref. 39.)

buprenorphine in association with benzodiazepines,[40] as well as cocaine and derivatives[41,42] before GC/MS. Seven diverse pharmaceuticals including caffeine, estradiol, ibuprofen, ketoprofen, musk ketone, naproxen, and triclosan were also more effectively derivatized using the BSTFA + TMCS combination as compared to TMSI.[43]

N-Methyl-*N*-trimethylsilyl-trifluoroacetamide (MSTFA) has similar donor strength to BSA and BSTFA but generates an even more volatile by-product, *N*-methyltrifluoroacetamide (Table 3, reagent 5). Both, excess MSTFA and the by-product, often elute with the solvent peak, eliminating the presence of extra peaks in the chromatogram. Cocaine and its metabolites, benzoylecgonine and ecgonine methyl ester, were sequentially derivatized first with methyl iodide to obtain the ester derivative and then MSTFA to form the *o*-TMS derivative.[44] The derivatized compounds were separated by GC using a methylphenylsilicone column and nitrogen–phosphorus detection. Again, TMCS can be added to MSTFA to promote the derivatization of amides and hindered amines and hydroxyl groups. After SPE, acidic pharmaceuticals such as salicylate, ibuprofen, naproxen, ketoprofen, and diclofenac, as well as carbamazepin, were derivatized with MSTFA + 10% TMCS and determined by GC/MS at nanogram per milliliter levels in wastewater.[45]

The strongest reagent for silylation of hydroxyl groups is TMSI (Table 3, reagent 6). It does not react with amines or amides and is effective for most steroids, including those with unhindered and highly hindered OH groups. It also reacts quickly and smoothly with carboxyl groups. The carboxylated tetrahydrocannabinol was first isolated from urine using a sulfonated polymer SPE cartridge before derivatization with TMSI to form the TMS derivative that could be detected in the range from 1 to 50 ng.[46]

Silyl imidazole compounds, other than those that derivatize with a TMS group, have also been used in conjunction with GC. Methyltestosterone was derivatized using either the dimethylethylsilyl (DMES)-imidazole or dimethylisopropylsilyl (DMIPS)-imidazole to the corresponding silyl ether derivative.[47] Reaction conditions involve heating at 70 °C for 1 h before removal of the excess reagent by N_2 and reconstitution of the residue in cyclohexane. Because the desired application was the assay of methyltestosterone in bulk powder and tablets, separation on a packed column was adequate in the concentration range 0.1–1.5 mg mL^{-1} (Figure 4a–c).

Alternatively, *N*-methyl-*N*-(*t*-butyldimethylsilyl)-trifluoroacetamide (MTBSTFA) derivatizes hydroxyl, carboxyl, thiol, and primary or secondary amine substituents by adding a *t*-butyldimethylsilyl (TBDMS) group. These TBDMS derivatives are more stable to hydrolysis than TMS compounds and, when analyzed by GC/MS, a strong M-57 fragment is noted, which can be used to determine the molecular weight of the original compound. These advantages have been demonstrated in

Figure 4 Typical gas chromatograms of (1) methyltestosterone and (2) norethandrolone as (a) TMS, (b) dimethylchlorosilane (DMCS), and (c) DMIPS derivatives. Note the bulkier derivatives are shifted to a cleaner area in the GC trace. (Reproduced with permission from Ref. 47.)

the determination of short- and long-chain carboxylic acids.[48] A factorial experimental design comparison showed MTBSTFA had a better overall performance than BSTFA for selected pharmaceuticals such as salicylate, ibuprofen, naproxen, propranolol, carbamazepine, and others.[49] Thirty drugs of abuse, including amphetamine-type drugs derivatized with HFAA, benzodiazepines and cannabinols with MTBSTFA, and buprenorphine with MSTFA were separated with fast temperature programming and a high flow rate on 30 m × 0.32 mm i.d. capillary columns after SPE from 250 μL of human oral fluid.[50] The same authors focused on the rapid separation of MTBSTFA derivatized benzodiazepines and other drugs (18 in all) in 4.40 min using a high initial column temperature, fast temperature programming, a thin stationary phase film thickness, and hydrogen as the carrier gas.[51] Limits of quantitation were from 1 to 100 ng mL^{-1}.

A wide variety of drugs including benzodiazepines, cannabinoids, opioids, antidepressants, antipsychotics, antiepileptics, and others were derivatized using a two-step MTBSTFA, MSTFA reaction sequence and the subsequent *t*-butyldimethyl silyl and TMS derivatives were determined by GC/MS.[52] A similar two-step derivatization approach was used for β-adrenoceptor ligands and methyl iodide in potassium carbonate and acetone methylated the diuretics before GC/MS of these mixtures in about 5 min using narrow bore capillary columns.[53] To enhance SPME using a polystyrene–divinylbenzene fiber, phenazone drugs were first acetylated on the nitrogen atom using acetic anhydride but then silylated with MTBSTFA, which removes the acetyl group to enhance GC/MS detection.[54]

Pentafluorophenyldimethylsilyl (flophemesyl) derivatives are often generated from steroids by reaction with flophemesylamine at room temperature for 15 min. This is a selective reaction with only primary and secondary hydroxyl groups in steroids reacting in the presence of unprotected ketone groups. GC with EC detection provides detection limits in the nanogram–picogram range. Flophemesyl derivatives also have favorable advantages for GC/MS, producing diagnostic ions that carry more of the current than TMS derivatives.[55]

2.4 Sample Handling

Generally, drugs are found in aqueous matrices such as urine and plasma; extraction with an organic solvent is required to isolate the drug in a nonaqueous solvent that is compatible with most derivatization reagents as well as to remove inorganic salts that are not compatible with GC. An alternative approach, direct derivatization, combines the extraction and derivatization steps together. Using this approach for drugs in untreated biological samples prior to GC analysis has the primary advantages of improved extractability of a derivatized polar compound as well as the avoidance of stability problems. Direct derivatization of drugs in untreated biological samples can mean not only derivatization in the sample matrix followed by extraction but also a two-phase reaction where the derivatization takes place in the organic phase while extraction of the analyte is continuing from the aqueous phase.[56] Extractive alkylation has been applied to valproic acid and ketoprofen, in which the tetrabutylammonium ion acted as the anion-pairing agent to pull the compound into the organic phase, where alkylation to generate the methyl or phenacyl derivative was possible. Phenolic compounds such as clioquinol have been determined in an analogous fashion. Acylation involving perfluorinated anhydrides and chloroformates has also been used for the determination of drugs such

as metanephrine and normetanephrine. Chloroformates can dealkylate tertiary amines to form stable carbamates.

SPME uses a fiber, usually fused silica coated with a stationary phase, to provide extraction, preconcentration, and sample introduction into a single step. The actual syringelike device has an outer septum-piercing needle and a plunger that is the fiber. The fiber can be inserted into a liquid sample matrix or the headspace above a solid or liquid sample. Upon equilibrium, analytes of interest are partitioned between the stationary phase of the fiber and the sample matrix or headspace. After analyte preconcentration into the fiber, the syringe device is inserted into the GC injection port where the analytes are thermally desorbed and swept onto the column for separation. For example, endocrine steroid hormones were extracted from biological and environmental samples using a polyacrylate fiber, which was then introduced into the headspace of a BSTFA solution to cause analyte derivatization before insertion into the GC injection port.[57] It has been reported that SPME, using a carboxene/polydimethylsiloxane fiber, can be effective for adsorption of both the fatty acid analyte and the derivatizing agent phenyltrimethylammonium hydroxide before fiber insertion into the GC injection port where methylation of the carboxylic acid analytes occurs.[58] The optimum sample–fiber interaction time was 20 min and the linearity of response for octyldecylcarboxylic acid was about 2 orders of magnitude from about 3×10^{-6} M. It would seem that this approach could also be applied to some drugs such as naproxen.

3 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

A variety of chemistries can be adopted for either pre- or postcolumn derivatization in conjunction with HPLC because either aqueous or organic solvent compatible reactions are possible. Postcolumn photochemical derivatization has the advantage of instrumental simplicity with no problems of pumping a reagent or detection background from the reagent. Most of the books reviewing fundamental reactions for pre- and postcolumn derivatization chemistry in conjunction with HPLC were published in the 1980s, which appears to have been the most active time for research in this field.[59–65] Many review articles have focused on postcolumn derivatization with HPLC.[66–73] Some specific review articles on derivatization chemistry of pharmaceutical compounds with HPLC have also been published.[74–78] Although the other articles do not try to be comprehensive, Ahuja[77] gave a virtually complete review of the topic up to 1979. Danielson et al.[78] published another fairly complete review covering the period 1979–1987, which is the basis for this part of the article. Again, a specific example and an overview for each major class of pharmaceutical compounds are given.

3.1 Alkaloids

Separation of atropine and ergotamine by normal-phase liquid chromatography (LC) followed by post-column ion-pair extraction with an aqueous solution of 9,10-dimethoxyanthracene-2-sulfonate has been reported.[79] The organic mobile phase was monitored fluorimetrically with detection limits of 40–100 ng. Conversely, methadone, phencyclidine, and their metabolites were separated by reversed-phase HPLC using 9,10-dimethoxyanthracene-2-sulfonic acid in the mobile phase.[80] The resultant ion pairs (Table 4, reagent 3) were extracted with chloroform postcolumn on-line and detected fluorimetrically with detection limits of 1–6 ng mL^{-1} in plasma. A precolumn ion-pair derivatization method for atropine, hyoscyamine, scopolamine, and ergotamine, involving picric acid and normal-phase chromatography, provided ultraviolet (UV) detection limits of about 200 ng.[81,82]

Morphine, which can be oxidized to the dimer pseudomorphine using alkaline hexacyanoferrate (III), has been detected fluorimetrically after this postcolumn reaction.[83] Other opiates, such as normorphine, naborphine, codeine, norcodeine, and others, were also reactive. The excitation and emission wavelengths were 323 and 432 nm respectively. The mobile phase, a 12.5 : 87.5 methanol–0.1 M KBr solution, was propelled through a C_{18} reversed-phase column. The derivatizing agent was 50 mg of $K_3Fe(CN)_6$ in 250 mL of 4 M ammonia solution delivered at 0.4 mL min^{-1}. The selectivity advantage of fluorescence over UV detection for the determination of morphine in urine and serum samples was definitive using the instrumentation shown in Figure 5. Morphine could be determined at the 2–30 μg mL^{-1} level in such biological samples with detection limits of about 10 ng. Fluorescence detection of morphine and related opiates was improved about twofold after postcolumn derivatization with alkaline hexacyanoferrate(III) and micelle formation with the nonionic surfactant Triton X.[84] A detection limit of 0.2 pmol was possible for morphine after precolumn dansylation.[85] The heroin metabolite 6-acetylmorphine has been determined in urine by reversed-phase HPLC with fluorescence detection after automated precolumn oxidation with hexacyanoferrate(III)[86] at a reported detection limit of 1 ppb. Reserpine, an antihypertensive agent, was detected fluorimetrically after postcolumn reaction with nitrous acid and UV irradiation.[87,88] Using

Table 4 Common fluorescent (F) and electrochemical (E) derivatives for HPLC

Number.	Compounds	Reagent(s)	Derivative
1	$R'NH_2$ (F)		2	RNH_2 (F)		3	R_3NH^+ (F)		4	RSH (F)		5	RCOOH (E)		6	Steroid (E)

this UV photochemical reaction, a 20-fold increase was found in the signal over the native fluorescence of reserpine.

Physostigmine, an acetylcholinesterase inhibitor, was separated from its degradation products and reacted with coulometrically generated bromine.[89] Electrochemical detection of unreacted bromine was inversely proportional to the amount of drug, and a detection limit of 0.5 ng could be attained. An on-line photochemical reaction detector caused decreased fluorescence of ergot alkaloids, permitting the identification of these compounds in complex chromatograms.[90] A similar system has been shown to convert cannabinol into a fluorescent derivative, providing detection limits of less than 1 ng in urine.[91] The use of this approach was extended for the detection of four Cinchona alkaloids and their dihydro derivatives as well as pyridoxine (vitamin B6) after isocratic reversed-phase separation.[92] On-line reaction of cannabinoids with fast blue salt B produced colored derivatives for detection at 490 nm.[93] Pilocarpine was quaternized with *p*-nitrobenzyl bromide before reversed-phase HPLC separation and detection at 254 nm.[94]

3.2 Amines

Primarily, fluorescent methods have been developed for amino acids and peptides. The *o*-phthalaldehyde (OPA), mercaptoethanol (or other thiol) reaction (Table 4, reagent 1) has been studied in both pre- and postcolumn modes; specific articles describing such chemistry with common amino acids are cited in general references.[59–62] Other amino acids such as *s*-carboxymethyl-L-cysteine,[95] baclofen,[96,97] and melphalan[98] have also been derivatized with OPA. Fourteen amino acids were determined fluorimetrically in 35 min by gradient reversed-phase LC after OPA prederivatization and sequential injection.[99] OPA with *N*-acetyl-L-cysteine effectively derivatized 20 amino acid enantiomers found in parental nutrition preparations prior to isocratic LC separation.[100] Carbowax SPME fibers were used to extract OPA-*N*-acetyl-L-cysteine derivatives of amphetamines from urine samples before chiral LC that established the enantiomeric composition at a low milligram per liter level.[101] Phanquinone (4,7-phenanthroline-5,6-dione) was used as a fluorogenic precolumn derivatizing agent for amino acids and was compared with the OPA method.[102] Although a longer reaction time of 60 min at a higher temperature of 60 °C was required for the phanquinone method, the derivative products were more stable. A more recent modification of this method is to use naphthalene-2,3-dicarboxyaldehyde with cyanide ion (Table 4, reagent 2).[103] Detection limits down to 200 fmol and improved stability of the derivatives were the stated advantages.

γ-Aminobutyric acid was modified with dansyl chloride before reversed-phase HPLC and fluorescent detection.[104] Detection at 360 nm was possible for *N*-acetylcysteine after reaction with 2,4-dinitro-1-fluorobenzene.[105] 1,2-Diamino-4,5-dimethoxybenzene was used to form a fluorescent derivative of *p*-hydroxybestatin.[106] A review of precolumn derivatization methods targeting only amino acids is available.[107] The peptide leupeptin was reacted through the guanidino moiety with benzoin to form a fluorescent derivative.[108] Felypressin, a nonapeptide, was derivatized with fluorescamine, providing detection limits of 0.3 ng.[109] A dinitrophthalic anhydride reaction of peptides permitted either electrochemical or absorbance detection.[110] An ion-pair detection technique has been applied to hydrophobic amino acids and peptides.[111]

A variety of other fluorescent methods have also been reported for specific drugs. Tranexamic acid has been detected using OPA.[112] Biogenic amines such as tyramine, tryptamine, and serotonin were reacted with OPA in a post-[113] or precolumn[114] mode. The OPA precolsumn fluorescent reaction has also been applied to L-buthionine-(*S*,*R*)-sulfoximine in plasma[115] and mexiletine.[116] Fluorescent derivatization with fluorescamine has been applied in the postcolumn mode for sulfapyridine[117] as well as in the precolumn mode for tocainide[118] and the antiepileptic drugs vigabatrin and gabapentin.[119] Enantiomers of mexiletine have also been resolved.[120] After conversion of the drug panthenol to aminopropanol, the fluorescamine reaction provided detection limits of 0.4 μg.[121] The determination of debrisoquine and its hydroxy metabolites was possible by reaction through the guanidine moiety to form fluorescent compounds.[122] A postcolumn photochemical reactor caused the cleavage of methotrexate to form the highly fluorescent 2,4-diaminopteridine-6-carboxyaldehyde.[123] Indolethylamines were condensed with an aldehyde or α-keto acid to form fluorescent carboline derivatives.[124] Thiamine (vitamin B_1) was oxidized with hexacyanoferrate(III) in base to give the fluorescent thiochrome in either the precolumn[125] or the postcolumn[126] mode. Riboflavin, already fluorescent, and thiamine, after precolumn oxidation to thiochrome using hexacyanoferrate(III), were determined by HPLC in a variety of food powders such as flour, milk, and beans.[127] Hydrazine compounds, such as isoniazid, were reacted with *m*-fluorobenzyl chloride before reversed-phase separation and detection at 220 nm.[128] A precolumn coumarin reaction permitted fluorescent detection of 5-fluoro-2′-deoxyuridine.[129] Fluorescein isothiocyanate (FITC) modified a bronchodilator before HPLC-fluorescence analysis.[130] Using excitation at 470 nm and emission at 537 nm, the 7-nitrobenzofurazan derivative of gabapentin

was determined by reversed-phase C_{18} silica LC with a limit of quantification of 2 ng mL^{-1} in human serum.[131]

Some UV derivatization methods have been developed for aliphatic and even aromatic amines. Phenylisothiocyanate (PITC) has been used as a precolumn derivatizing agent for amino acids in conjunction with reversed-phase HPLC. Both primary and secondary amines can react with PITC (Table 5, reagent 1(B)) and the aromatic tag provides good retention for the smaller amino acids.[132] Both primary and secondary amines were derivatized with 9-fluorenylmethyl chloroformate (FMOC) before separation by reversed-phase HPLC with UV detection at 254 nm. After SPE of a urine sample, β-phenethylamine was determined with a detection limit of 0.1 ng mL^{-1}.[133] Amphetamine and methamphetamine have been reacted with 4-methoxybenzoyl chloride (Table 5, reagent 1(A)) and other acid chlorides for subsequent UV detection.[134] A comparison of methods for amphetamines has been made.[135] The enantiomeric separation of (−)-1-(9-fluorenyl)ethyl chloroformate chiral derivatives of primary and secondary amphetamines was possible either by UV or fluorescence detection with resolution ranging from 0.9 to about 2.[136] The cardiotonic drug heptaminol has been derivatized with aminoazobenzene-4-isothiocyanate for UV detection at 420 nm[137] or OPA for electrochemical detection.[138] Secondary amines, such as piperazines, were converted into UV derivatives with *m*-toluoylacyl chloride.[139] Enantiomers of metoprolol have been separated after reaction with the chiral reagent (*S*)-(−)-phenylethyl isocyanate.[140] The determination of isophenindamine in the presence of phenindamine

Table 5 Common UV derivatives for HPLC

tartrate has been achieved by forming charge transfer complexes using $AgNO_3$ and reversed-phase HPLC.[141]

Antihistamines and other pharmaceuticals with a tertiary amine moiety have been derivatized to provide for luminescence detection. An ion-pair extraction detector using dimethoxyanthracene sulfonate (Table 4, reagent 3) has permitted the fluorescent determination of tertiary amines, such as bromopheniramine and chlorpheniramine,[142,143] ephedrine,[144] and hyoscyamine.[145,146] with detection limits of 200–500 pg. Precolumn reaction of chlorpheniramine with benzyl chloroformate gives a fluorescent derivative with a detection limit of 0.1 ng mL^{-1}.[147] Antihistamines, such as diphenhydramine, were converted through the tertiary amine group into fluorescent derivatives using 2-naphthyl chloroformate.[148] Aliphatic tertiary amines can be determined at the picomole level by postcolumn chemiluminescent detection, using tris(bipyridyl)ruthenium(III).[149] This topic of postcolumn electrochemiluminescence detection has been reviewed for both LC and CE.[150] Antihistamines in urine have also been separated by HPLC and detected with good selectivity using this ruthenium metal complex (Figure 6a–c).[151] Tamoxifen and its metabolites in human serum can be UV photochemically activated to form fluorescent phenanthrenes.[152] Postcolumn UV irradiation of tamoxifen and its derivatives caused rearrangement to a substituted phenanthrene, permitting fluorescent detection with 0.1 ng mL^{-1} detection limits.[153] Several analgesic compounds such as phenazone, propylphenazone, and dimethylaminophenazone, as well as their metabolites, were derivatized in situ with acetic anhydride to make more hydrophobic compounds that could be isolated from the sample matrix using SPE, before their separation by LC/MS/MS.[154]

Derivatives of nicotine, cotinine, and other metabolites in urine after HPLC separation can be detected at 530 nm by using diethylthiobarbituric acid as a color-forming agent.[155] Nicotinic acid and niacinamide were derivatized through the hetereocyclic nitrogen using cyanogen bromide and then an arylamine to give polymethine dyes, which were separated by micellar LC.[156] DL-Carnitine and acetyl-DL-carnitine were reacted with (α-bromo)methylphenyl ketone to form chiral derivatives that were separated on a chiral LC column to determine the enantiomeric purity of the L form.[157] Racemic phenothiazines were *N*-demethylated with vinyl chloroformate to form their secondary amines, which could then be reacted with (*R*)-(+)-1-phenylethyl isocyanate (Table 5, reagent 3), and these compounds were separated by reversed-phase HPLC.[158] Tertiary tetrahydroisoquinolines, such as diclofensine, were oxidized before photochemical conversion to fluorescent isoquinolinium derivatives.[159] After postcolumn ion-pair extraction of

Figure 6 Chromatograms of an undiluted urine sample spiked with (A) 0.15 μg mL^{-1} pheniramine, (B) 0.26 μg mL^{-1} bromopheniramine, and (C) 0.29 μg mL^{-1} diphenhydramine taken with (a) UV (214 nm), (b) UV (254 nm), and (c) Ru $(bpy)_3^{3+}$ chemiluminescence detection. (Reproduced with permission from Ref. 151.)

secoverine, peroxylate chemiluminescence (CL) detection was carried out.[160]

Postcolumn detection of platinum(II) antineoplastic agents such as cisplatin is possible, as shown in Figure 7. The cisplatin-derived species are first reacted with an oxidant such as dichromate to form an activated species, which then combines rapidly with bisulfate to give a UV-absorbing complex. Using knitted open-tubular reactors, delay times of 26 s for the dichromate reaction and 4.7 min for the bisulfate reaction were found to be optimal. Figure 8(b) shows the substantial improvement in absorbance response of the separated derivatives as compared to the detection (Figure 8a) of the unmodified platinum compounds. Detection limits of 5–10 μg mL^{-1} were possible. Cisplatin was also determined in a plasma ultrafiltrate sample at the 5-ng level.[161]

3.3 Antibiotics

This class of pharmaceuticals has received major attention for both pre- and postcolumn derivatization. Fluorescent derivatization of the primary amine group of

Figure 8 Comparison of UV detection (300 nm) after HPLC separation (a) and reactor response (290 nm) to derivatized platinum (b) for a mixture of *cis*-dichloroplatinum complexes: (1) *cis*-dichloro(1,2-diaminocyclohexane)platinum(II), (2) *cis*-dichloro(ethylenediamine)platinum(II), and (3) *cis*-dichlorodiammineplatinum(II). (Reproduced with permission from Ref. 161.)

many antibiotics with OPA and a sulfhydryl compound, often mercaptoethanol, has been commonly performed (Table 4, reagent 1). Gentamicin,[162,163] penicillin V, after enzymatic conversion to 6-aminopenicillanic acid,[163] penicillin N,[164] cephalosporin C,[165] cycloserine,[166] and fludalanine[167] were assayed by using an OPA postcolumn reactor. Spectinomycin, after postcolumn oxidation with hypochlorite, could also be derivatized with OPA in a second reaction coil.[168] Reversed-phase separation was employed for all these separations because the OPA reaction is carried out in an alkaline buffer solution. Precolumn reactions with OPA for gentamicin,[169] sisomicin,[170] and phosphinothricin and its alanine analog[171,172] before reversed-phase separation have all been reported. Amikacin isomers were first adsorbed on a silica gel column before reaction with OPA; the derivatives were eluted with ethanol before separation by reversed-phase HPLC.[173] A comparison of pre- and postcolumn OPA reaction conditions for gentamicin has been made.[174] For all these OPA fluorescence methods, detection limits are about 1 μg mL^{-1}. For example, β-lactams found in microbial fermentation broths were separated on a C_{18} HPLC column and detected fluorimetrically with excitation at 350 nm and emission at 450 nm after reaction with OPA and mercaptoethanol. Cephamycin, penicillin N, cephalosporin C, and 6-aminopenicillanic acid were separated in about 12 min at a flow rate of 1.5 mL min^{-1} with postcolumn conditions involving the OPA reagent at pH 12, a reaction coil of 12 m, a temperature of 90 °C, and a reagent flow rate of 0.8 mL min^{-1}. Detection limits of less than 0.5 and 1.0 μg mL^{-1} were achieved for penicillin N and cephalosporin C respectively.[175]

Numerous other postcolumn UV, fluorimetric, and electrochemical methods have been reported for tetracycline-type antibiotics and related compounds. Formation of a mercuric mercaptide of penicillins permits UV detection at 310 nm with detection limits of 10 ng.[176] Sulfonamides in egg, milk, and meat samples have been detected at 450 nm after derivatization with *p*-dimethylaminobenzaldehyde.[177] Monensin, narasin, and salinomycin in animal feeds have been reacted with vanillin to give products detectable at 520 nm.[178] Penicillins, such as amoxicillin, ampicillin, and others, can be separated by reversed-phase HPLC with alkaline degradation in the presence of mercuric chloride[179] (Table 5, reagent 6). Methanol promotes this reaction, forming the ring-cleaved product, which absorbs at 274 nm, and is detectable at 50 ng mL^{-1}. It was discovered later that sodium hypochlorite could replace the mercuric chloride reagent while maintaining a 1-min hydrolysis time.[180] Application of this latter method to penicillins in biological samples has been made.[181,182] Fluorescent detection of streptomycin reacted through the guanidino groups with naphthoquinone-4-sulfonate in alkaline solution has been reported in serum samples.[183] Photothermal derivatization of ciprofloxacin and its metabolites permits fluorescent detection throughout a linear range of about 2–1000 ng mL^{-1}.[184]

Photolysis with electrochemical detection of penicillins and cefoperazone has provided detection limits of about 6 ng.[185] Tetracycline, oxytetracycline, chlorotetracycline, demeclocycline, doxycycline, and meclocycline were separated on a C_{18} column and then photoirradiated before chemiluminescent detection with rhodamine and cerium(IV).[186] Detection limits in the 0.1–0.3 ng mL^{-1} range were reported. Electrochemically generated bromine was used as an oxidizing agent for cephalosporins and their decomposition products.[187] The excess bromine was detected at 0.4 V using a glassy carbon electrode. A comparison of this method with UV detection and postcolumn fluorescamine derivatization has recently been summarized.[188] Acidification of a serum sample sometimes improved recovery of cephalosporins when micellar chromatography was used with sodium dodecyl sulfate (SDS) in the mobile phase.[189] Fluorescamine has been used in an automated system for amoxycillin in biological fluids.[190] CL detection of clindamycin phosphate using tris(bipyridyl)ruthenium(III)[191] gave detection limits of 8 ppb compared to 970 ppb using UV detection at 214 nm.

A variety of reagents are also available for precolumn derivatization of antibiotics and UV or fluorimetric detection. Phenacyl esters of some natural penicillins were prepared using dibromoacetophenone before reversed-phase HPLC with UV detection.[192] Nitrobenzene derivatives of neomycin B and C can be separated by normal-phase HPLC and detected at 350 nm.[193] Similar methods using 1-fluoro-2,4-dinitrobenzene to form 2,4-dinitrophenyl derivatives of neomycin B and C[194,195] and amikacin[196,197] have also been published. Neomycin and other aminoglycosides have been converted to benzoyl derivatives before UV detection at 230 nm.[198] Aminoglyosides have also been reacted with 2,4,6-trinitrobenzenesulfonic acid, permitting UV detection at 350 nm.[199] Ion-pair formation of methscopolamine bromide with an aromatic anion during reversed-phase HPLC permitted UV detection.[200] The secondary amine group of spectinomycin was derivatized with 2-naphthalenesulfonyl chloride (Table 5, reagent 2) before normal-phase HPLC and UV detection at 254 nm.[201] Nitrofurantoin drugs furazolidone, nitrofurazone, furaladone, and nitrofurantoin were hydrolyzed and the released side chains derivatized with 2-nitrobenzaldehyde before SPE and determination by LC/MS with atmospheric chemical ionization.[202] Nitrofurantoin antibiotics and metabolites in honey were also determined as 2-nitrobenzaldehyde derivatives by LC/MS/MS and the predominant compound was found to be furazolidone.[203]

The reagent FMOC formed fluorescent derivatives of natural penicillins, cephalosporins, and their precursors in biological samples.[204] β-Lactams were prederivatized with FMOC for 5 min at 20 °C in a borate buffer at pH 7.7 before injection of the derivatives onto a C_{18} reversed-phase column. Excitation and emission wavelengths for the fluorescent detection were 260 and 313 nm respectively. A typical chromatogram is given in Figure 9, showing the modest acetonitrile gradient until after elution of ampicillin in which the acetonitrile is taken to 100%. Detection limits were 0.01 and 0.05 $\mu g\,mL^{-1}$ for 6-aminopenicillanic acid and isopenicillin N, respectively. Application of the method to fermentation broths was made over a range of 0.05–100 $\mu g\,mL^{-1}$. A maleimide reagent gave a fluorescent derivative for penicillamine.[205] An imidazole–mercuric chloride reagent can convert penicillins into mercury stabilized penicillanic acids after reaction at 50 °C for 50 min prior to UV detection at 325 nm.[206] A comparison of this method with the postcolumn OPA fluorescence method has been made.[207] A similar method using 1,2,4-triazole and Hg(II) for ampicillin, amoxicillin, and other antibiotics has been studied.[208–210] Two precolumn derivatization studies with UV detection were checked with real samples. Tobramycin plus the impurities neamine and kanamycin and also the degradation product nebramine were derivatized with 2,4-dinitrofluorobenzene for 20 min at 70 °C in 0.8-mM sulfuric acid. Separation of the derivatives on a C_{18} column with detection at 365 nm was carried out, and the stability of tobramycin in ophthalmic solutions was determined.[211]

3.4 Barbiturates

Precolumn methods primarily include reaction with various alkylating reagents. The highly reactive chlorine of *N*-chloromethylphthalimides permits derivatization of OH and NH functional groups to form UV-absorbing compounds.[212] Detection limits of 5 ng for phenobarbital have been reported.[213]

2-Naphthacyl bromide forms strongly absorbing derivatives of barbiturates at 254 nm with detection in plasma or serum below the therapeutic range.[214] An on-line solid-phase anion-exchange extraction provided enhanced chromatographic selectivity of barbiturates in urine.[215] Postcolumn UV detection of barbiturates can be conveniently enhanced by mixing with a pH 10 borate buffer.[216,217] A wavelength shift for maximum absorbance from 220 to 240 nm provides for detection limits of about 6 μg for butabarbital.

The UV detection of barbiturates can be significantly enhanced through postcolumn photochemical derivatization. Barbiturates have no significant absorbance above 230 nm and detection in the 200–220 nm range can be complicated by the presence of interfering peaks, particularly in biological samples such as serum. Using a 25 m × 0.25 mm i.d. Teflon-knitted open-tubular reactor mounted around a mercury lamp, which provided an irradiation time of about 190 s, excellent signal enhancement at 270 nm was possible for barbiturates (Figure 10a and b). It was determined by HPLC that dealkylation at the 5-position to give ethylbarbituric acid was the mechanism of the photochemical reaction.[218]

Figure 10 Chromatogram of a standard sample of barbiturates detected at 270 nm, (a) without and (b) with on-line photochemical reaction. (1) Aprobarbital; (2) butethal; (3) pentobarbital; (4) mephobarbital; and (5) secobarbital. (Reproduced with permission from Ref. 218.)

3.5 Carbonyl Compounds and Carboxylic Acids

First, a short summary of the methods involving the reduction of quinone compounds to form fluorescent hydroxy derivatives is given. Vitamin K_1 in human plasma was electrochemically reduced at −0.4 V and the fluorescent derivative detected at levels as low as 25–50 pg.[219] Comparison of this method with UV and electrochemical oxidation detection systems has been made.[220] Danthron (1,8-dihydroxyanthraquinone) has been reduced with dithionite and determined by either flow injection analysis in Modane tablets or HPLC in urine.[221] A comparison of UV and fluorescence chromatograms for danthron spiked in a urine sample showed the selectivity advantage of fluorescence (Figure 11a and b). Dansylhydrazine formed fluorescent derivatives of tetraphenylacetone isomers before separation.[222] Short-chain carboxylic acids were modified using *p*-bromophenacyl bromide (Table 5, reagent 4) to form esters that could be easily detected by UV absorbance.[223]

5-Bromomethylfluorescein was studied for the prederivatization of carboxylic acids for detection by either UV absorbance or fluorescence (standard and laser induced). Model analytes included prostaglandins (unsaturated carboxylic acids) and the drug cefuroxime, and also standard aliphatic and aromatic carboxylic acids. Dicarboxylic acids did not react with bromomethylfluorescein, possibly due to solubility problems in the organic reaction medium.[224] Fatty acids and prostaglandins were converted into *p*-hydroxanilides using *p*-aminophenol (Table 4, reagent 5). These hydroxy derivatives were then oxidized through electrochemical detection after reversed-phase HPLC.[225] A UV-absorbing naphthacyl ester of the prostaglandin carboprost has been formed before normal-phase HPLC.[226] Fluorescent derivatives of prostaglandins using 9-anthryldiazomethane provided detection limits of 100 pg after reversed-phase HPLC.[227] The prostaglandin arbaprostil was derivatized with panacyl bromide before column switching using fluorescent derivatization.[228,229] Prostaglandins have also been derivatized with *p*-(9-anthroyloxyl)phenacyl bromide.[230] Oxidation of prostaglandins to the corresponding 15-oxo derivatives using pyridinium dichromate permitted UV detection at 228 nm and picomole detection limits.[231,232] Prostaglandins have been labeled with the fluorescent reagent 9-anthyldiazomethane through the carboxyl group. This esterification reaction can be carried out under mild conditions such as 40 °C for 30 min. Five prostaglandin derivatives were separated by reversed-phase HPLC using fluorescent detection with

Figure 11 Separation of danthron spiked in urine (2 ng mL^{-1}). (a) UV detection (254 nm). Column, 250 × 4.6 mm C_{18}; mobile phase, 60 : 40 methanol–water at 1.2 mL min^{-1}. (b) Fluorescence detection (388-nm excitation, 510-nm emission). A solution of 90-mM dithionite in 2% borate buffer was pumped into the effluent at 0.4 mL min^{-1}, AUFS–Absorbance units full scale. (Reproduced with permission from Ref. 221.)

excitation at 365 nm and emission at 418 nm at the 8-ng level.[233]

Ascorbic acid from 5 to 800 mg L^{-1} was detected by CL after postcolumn reaction with lucigenin.[234] After derivatization with 1,2-phenylenediamine, both ascorbic acid and dehydroascorbic acid were separated by reversed-phase ion-pair HPLC.[235] The same two compounds were separated by reversed-phase HPLC, and the dehydroascorbic acid was reduced to ascorbic acid with dithiothreitol for UV detection at 267 nm.[236] UV detection of bis(dinitrophenyl)hydrazine derivatives of ascorbic and dehydroascorbic acid was possible at 497 nm.[237] Four forms of ascorbic acid, the previous two plus isoascorbic acid and its dehydro form, were detected postcolumn using benzamidine and fluorescence.[238] Total ascorbic acid was determined fluorimetrically after reaction with diaminodimethoxybenzene.[239]

A number of methods directed toward pain relievers and other compounds with carbonyl groups have been published. Indomethacin formed a fluorescent derivative after postcolumn alkaline hydrolysis, giving a detection limit of 5 pg.[240] Postcolumn alkaline hydrolysis has also been applied to aspirin in plasma in order to form the fluorescent salicylic acid.[241] A wide variety of acidic compounds including acetylsalicylate, ibuprofen, ketoprofen, naproxen, benzafibrate, diclofenac, and tolfenamic acid were determined by HPLC with postcolumn photochemical reaction and fluorescence at the 2–120 ng mL^{-1} level.[242] The enantiomeric composition of ibuprofen in human plasma has been resolved after prederivatization with (*S*)-(−)-1-(naphthenyl)ethylamine[243] or ethyl chloroformate–leucinamide.[244] Flunoxaprofen enantiomers have been separated after reaction with (*S*)-(−)-1-phenylethylamine.[245] Artesunic acid was determined after derivatization with *o*,*p*-nitrobenzyl-*N*,*N*′-diisopropylisourea by HPLC with UV detection.[246] Carnitine, betaine, and related compounds have been reacted to form either 4′-bromophenacyl esters[247] or *p*-nitrobenzyl oxines[248] to permit UV detection at 254 nm. A new acridinium sulfonylamide label permits the chemiluminescent detection of carboxylic acids such as the test compound ibuprofan. This alkylation reaction takes place in dry acetonitrile for 20 min at 50 °C and separation of the derivative is possible on a C_{18} column with an acetonitrile–water–tetrahydrofuran mobile phase with the ion-pairing agent tetrabutylammonium ion. CL detection of the acridinium label is possible by postcolumn addition of potassium hydroxide solution. A detection limit of 60 pg of derivatized ibuprofen was found.[249]

The formation of multiple molecular ions from various alkali metals in LC/MS can reduce reproducibility and make sensitive quantitation difficult. The addition of a primary alkylamine to the mobile phase can cause preferential formation of the alkylammonium adduct ion and suppression of other multiple molecular ions. Octylamine was particularly advantageous in improving the detectability of paclitaxel and docetaxel by about a factor of 4–5 down to about 0.5–1.0 ng mL^{-1}.[250] A similar enhancement was reported for a 3-benzothiepine compound TAK-778 using 1-hexylamine; interaction of the alkyl amine with the phosphoryl group was postulated.[251] Methylammonium acetate was effective in improving the MS sensitivity for simvastin and its hydroxy acid degradation product.[252] Twelve acidic pharmaceuticals and triclosan were determined by ion-pair lC using tri-*n*-butylamine and electrospray ionization-MS.[253] The ion-pairing agent increased the MS signal intensity, permitting detection limits in the 6–200 ng L^{-1} range.

3.6 Catecholamines

Precolumn fluorescent derivatization of catecholamines with OPA and a thiol has been well established (Table 4, reagent 1). Norepinephrine, dopamine, and normetanephrine have been measured at the low picogram level after reversed-phase HPLC.[254,255] An

electrochemical cell placed between the injector and the column was used for oxidation of adrenaline and levodopa to the corresponding quinones for detection in the visible region.[256] Resolution of norephedrine enantiomers after derivatization with either acetylglycosyl isothiocyanates[257] or 4-methyl-5-phenyl-2-oxazolidone[258] has been reported. Fluorescent catecholamine derivatives have been generated using 1,2-diphenylethylenediamine, providing detection limits in the femtomole range.[259]

Postcolumn fluorescent reaction of norepinephrine and epinephrine with trihydroxyindole provided 20–30 pg detection limits.[260] This method was compared with the OPA–thiol reaction in the postcolumn mode.[261,262] The same two catecholamines can be converted into fluorescent products by heating in an alkaline borate buffer after ion-exchange chromatography.[263] Dopamine isomers in serum and urine have been separated before hydrolysis and reaction with *p*-aminobenzoic acid to form fluorescent products.[264] Glycylglycine as an alternative postcolumn reagent to glycinamide increased the rate of formation of fluorescent derivatives after ion-exchange HPLC.[265,266] Catecholamines catalyze the reaction between formaldehyde and *o*-dintrobenzene and permit their detection at 560 nm.[267]

3.7 Hydroxy Compounds

Most precolumn methods focus on enhancing UV detection. Isotachysterol derivatives of vitamin D improved detection at 290 nm after normal-phase HPLC.[268] On-column periodate oxidation of ephedrine sulfate, a nasal decongestant, to form benzyl alcohol has been carried out in a seven-laboratory study.[269] Indirect photometric detection using *n*-heptyl *p*-aminobenzoate in the mobile phase and a C_{18} column has been applied to menthol.[270] Enantiomers of propranolol and 4-hydroxypropranolol were formed upon derivatization with (+)-1-phenylethyl isocyanate[271] or (+)-tetraacetyl β-D-glucopyranosyl isothiocyanate[272,273] and separated by reversed-phase HPLC. Enantiomers of derivatized or underivatized propranolol have been separated.[274] Diastereomeric derivatization of 1-methyl-3-pyrolidinol[275] and proxyphylline[276] for UV detection has been accomplished. Qinghaosu, an antimalaria component in a Chinese herb, can be converted into a UV-absorbing compound using a sodium hydroxide solution before HPLC separation.[277] A derivative of qinghaosu has been esterified with diacetyldihydrofluorescein before HPLC and UV detection.[278] Cholic acid and its derivatives have been labeled with 1-anthroylnitrile before HPLC and fluorescent detection at the femtomole level.[279] Trospium has been converted into the corresponding spiro alcohol before fluorescent derivatization with benoxaprofen chloride and reversed-phase HPLC.[280]

Derivatization can be an effective method to facilitate the chiral separation of pharmaceuticals. Nadolol diastereomers were derivatized with (*R*)-(−)-1-(1-naphthyl)ethyl isothiocyanate to chiral urea derivatives through the secondary amine group by reaction for 5 min at 45 °C. Separation of the RS, SR, RR, and SS diastereomers was straightforward on a C_{18} column using a 60 : 40 water–acetonitrile mobile phase (Figure 12a–c). Fluorescence detection with excitation at 285 nm and emission at 340 nm provided selectivity for the determination of nadolol in plasma samples. The limit of detection was 2.5 ng mL^{-1}, representing 50 pg injected. This chiral derivatization method has been used for the determination of enantiomers of other β-blocker drugs.[281]

A few of the postcolumn approaches are outlined below. Using a photochemical reactor, diethylstilbestrol (DES) has been converted into a fluorescent derivative and determined at the low parts-per-billion level in biological matrixes.[282,283] Anabolic stilbenes, such as DES, have been measured in urine by HPLC and an off-line CL immunochemical assay.[284] The antihypertensive agent fenoldopam was formed using a postcolumn enzyme reactor from the corresponding glucuronide, and detected electrochemically.[285] Cyclodextrins in biological fluids were assayed by negative colorimetric detection after postcolumn complexation with phenolphthalein.[286] Vitamin B_6 (pyridoxine) has been postcolumn derivatized with 2,6-dibromoquinone-4-chlorimide to form a colored product with a maximum absorbance at 650 nm.[287]

3.8 Steroids

Esterified estrogens were converted into their free phenolic forms by acid hydrolysis, and separation could be achieved by reversed-phase HPLC.[288] The chromatographic behavior of estrogen carbonyls, such as equilenin, equilin, and estrone, was improved upon reduction to the 17-α-hydroxy compounds using sodium borohydride.[289] Prederivatization of conjugated estrogens with dansyl chloride permitted fluorescent detection after separation by normal-phase HPLC (Table 4).[290] This method was modified by having the dansylation prederivatization reaction with the estrogens occur on the SPE column before determination by HPLC with MS/MS detection at the parts-per-trillion level.[291] Ketosteroids, such as androsterone, dehydroepiandrosterone, epiandosterone, and etiocholanolone, were derivatized with *p*-nitrophenylhydrazine (Table 4, reaction 6) and detected electrochemically at levels as low as 200 pg.[292]

Isonicotinoyl hydrazine was used to tag steroids, such as corticosterone, to permit fluorescent detection after normal-phase HPLC.[293] Further work using this

Figure 12 Typical chromatograms of (a) blank control dog plasma, (b) plasma spiked with 50 ng mL^{-1} of each diastereomer, and (c) plasma obtained 2 h after oral administration of 1 mg kg^{-1} of racemic nadolol. Peaks: 1 = (*SR*)-nadolol; 2 = (*RS*)-nadolol; 3 = (*RR*)-nadolol; and 4 = (*S*, *S*)-nadolol. (Reproduced with permission from Ref. 281.)

method with reversed-phase HPLC and optimized reaction conditions permitted detection limits as low as 7–10 ng.[294,295] 17-Oxosteroids were labeled with dansylhydrazine and then chromatographed on a silica column with subsequent fluorescent detection from 60 to 100 pg.[296] A similar method for this class of compounds using 3-chloroformyl-7-methoxycoumarin and reversed-phase HPLC has been published.[297] Hydroxysteroids were derivatized with anthroylnitrile, showing the feasibility of the reaction for fluorescent detection after HPLC.[298]

Six corticosteroids were separated within 25 min and reacted with a lucigenin–KOH solution for CL detection.[299] The reactive site is an α-hydroxycarbonyl group, and detection limits of 2 pg were comparable to those with precolumn fluorescent methods. Corticosteroids were also derivatized postcolumn with glycinamide in the presence of hexacyanoferrate(III) before fluorimetric detection at the 5-ng level.[300] Digoxin, a widely used cardiac glycoside, has been detected fluorimetrically by postcolumn reaction with a solution of ascorbic acid, peroxide, and HCl.[301,302] A detection limit of less than 1 ng was attained.

Digoxin and its metabolites, such as digoxigenin, were derivatized with 1-naphthoyl chloride before separation and fluorescent detection,[303] and 5 ng amounts could be determined in urine or feces. A similar method using 4-nitrobenzoyl chloride has been reported.[304] Dihydrodigoxin, a major metabolite of digoxin, has been separated from digoxin with dual UV and postcolumn fluorescent derivatization detection.[305] The photoreduction of anthroquinone-2,6-disulfonate to the fluorescent 9,10-dihydroxyanthracene-2,6-disulfonate occurs only in the presence of hydrogen atom-donating substrates, such as alcohols, aldehydes, amines, ethers, and saccharides. Using a knitted Teflon reactor, cardiac glycosides, such as digoxin, digoxigenin, and diginatin, have been determined in the range 50–500 ng.[306]

3.9 Sulfur Compounds

Most methods employ a precolumn reaction to form fluorescent or UV derivatives. Dansylaziridine[307] was used to determine cysteine and other thiols. Biological thiols, such as glutathione and ergothioneine, were reacted with monobromobimane (Table 4, reagent 4) before ion-exchange chromatography.[308] This method was also adopted for the determination of dithiols, such as 2,3-dimercaptopropane-1-sulfonic acid, in urine at levels as low as 10 pmol.[309] Fluorescent derivatization of 2-mercaptopropionylglycine using *N*-(7-dimethylamino-4-methyl-3-coumarinyl)maleimide could probably be extended to other thiol compounds.[310] Resolution of the optical isomers of diltiazem was accomplished using UV detection after derivatization with optically pure 2-naphthylsulfonyl-2-pyrollidinecarbonyl chloride.[311] Three N-substituted maleimides were compared for precolumn derivatization of thiols such as penicillamine before electrochemical detection at the picogram level.[312] Ethacrynic acid (Table 5, reagent 5) forms UV-detectable derivatives of thiols, such as captopril, *N*-acetyl-L-cysteine, and mercaptopropionylglycine with detection limits as low as 0.5 μg mL^{-1}.[313]

Postcolumn derivatization of thioethers, such as ampicillin and ranitidine, was accomplished using on-line generated bromine and electrochemical detection of the excess bromine.[314] An analogous method has been reported for phenothiazines, such as thioridazine;

however, the resultant products from the oxidation reaction with bromine are detected fluorimetrically.[315] Photochemical activation of phenothiazines and demoxepam in 2 min and subsequent fluorescence detection provided detection limits a factor of 10 better than UV detection.[316] Applications of photochemical reactors to a variety of pharmaceuticals, such as phenothiazines, have been summarized.[317,318] A precolumn derivatization method for phenothiazine involves desulfurization with Raney nickel to produce diphenylamine, which is electrochemically active.[319] A detection limit of 10 pg was found. The reagent pyrenemaleimide provided derivatization of *N*-acetylcysteine with a detection limit of 10 pmol.[320] Postcolumn complexation of disulfiram and two of its metabolites using Cu^{2+} allowed colorimetric detection at 435 nm with detection limits in the low parts-per-billion range.[321] Quenched peroxalate CL has been employed using immobilized reagents in a postcolumn reactor for thioridazin, sulforidazine, and methimazole.[322]

On-line precolumn derivatization to improve reproducibility has been demonstrated for the determination of busulfan in human serum. A schematic diagram of the HPLC system is shown in Figure 13; all three columns C1, C2, and C3 were C_{18} type with different lengths and/or diameters. After extraction of busulfan from serum, the residue reconstituted in water was injected

Figure 13 Schematic diagram of the HPLC system. P(A), P(B), and P(C) = pumps; AS = autosampler; VAL 1 and VAL 2 = six–port valves 1 and 2; C0 = clean-up column; Cl, C2, and C3 = columns 1, 2, and 3; DET(A) and DET(B) = UV detectors A and B; MP (A), MP (B), and MP (C) = mobile phases A, B, and C. The solid and dotted lines in the six-port valves indicate valve positions 0 and 1 respectively. (Reproduced with permission from Ref. 323.)

Figure 14 Typical chromatograms of (a) drug-free serum and (b) serum spiked with busulfan (100 ng mL^{-1}) obtained with columns Cl, C2, and C3. The arrow indicates the retention time of the busulfan derivative. (Reproduced with permission from Ref. 323.)

on to C1, where it was derivatized with diethyldithiocarbamate (DCC) in mobile phase A for 5 min. Then the busulfan–DCC derivative from C1 was backflushed on to C2, where it was separated using mobile phase B. Because the background interference from mostly excess DCC overlapped the busulfan–DCC derivative peak completely, valve 2 was used to take a heart cut of this peak of interest and inject it on to C3. The resulting separation using mobile phase C is shown in Figure 14(a) and (b). Detection was at 278 nm and the lower limit of quantitation in serum was 10 ng mL^{-1}. The total time for the derivatization and separation was 33 min.[323] Alternatively, for therapeutic drug monitoring in plasma down to 10 ng mL^{-1}, the determination of busulfan was based on conversion to 1,4-diiodobutane prior to HPLC separation and then UV detection of the iodide formed upon postcolumn photolysis.[324]

4 CAPILLARY ELECTROPHORESIS

CE has developed into a versatile separation technique well suited for the determination of pharmaceutical and biomedical samples. The major advantages of CE over chromatographic separation techniques are its simplicity and efficiency. However, CE suffers from poor concentration sensitivity in detection owing to the extremely small sample volume involved. One way to improve the detection of charged analytes with weak chromophores is to use indirect detection in which an easily detected agent of the same charge is added to the running electrolyte. Replacement of the

visualizing agent by the analytes generates negative peaks as the readout. For example, the antiepiletic drug vigabatrin has poor UV absorptivity but can be determined in dosage forms from 5 to 150 mg L^{-1} using benzyltriethylammonium hydroxide as the visualizing agent.[325] To permit application of a negative voltage, the presence of cetyl trimethylammoniumbromide was required in the running electrolyte but the analyte of interest, valproic acid, could still be visualized as the anion with benzoate at 210 nm over the 1–100 mg L^{-1} range.[326] A similar approach was used to determine gabapentin using 5-sulfosalicylate as the visualizing agent.[327] CE separation and indirect laser-induced fluorescence (LIF) detection of diuretics ethacrynic acid, chlorthalidone, bendroflumethiazide, and bumetanide using fluorescein as the visualizing agent was possible in 3 min with a detection limit of 0.2 mg L^{-1}.[328] A more standard approach to improve the sensitivity of CE detection is to derivatize the analytes with more favorable detection characteristics by adding either an ultraviolet/visible (UV/vis) chromophore or a fluorophore.

Derivatization chemistry previously developed for HPLC is often applicable to CE.[329] At least one comprehensive review specifically focused on the derivatization in CE has appeared.[330] Several other review articles dealt with more specific topics, such as postcolumn luminescence derivatization,[331] CL derivatization[332] diastereomer derivatization,[333] and dyes used to derivatize molecules for CE with LIF detection in drug analysis.[334] The pros and cons of the various modes of derivatization and a detailed comparison of this topic between LC and CE can be found in the literature.[330] Instead of listing the derivatization reagents suited for labeling amino, aldehyde, keto, carboxyl, hydroxyl, and sulfhydryl groups, we intend to focus on the purpose of derivatization in CE from a practical point of view, i.e. enhancing the detectability. Since UV/vis and LIF are the most common detection approaches used in CE for pharmaceutical analysis, the most recent work related to these methods is primarily discussed below. Sections on special applications and derivatization instrumental modes are also included.

4.1 Derivatization for Ultraviolet Detection

Although most organic compounds have UV/vis chromophores and CE detection is possible at 200 nm, derivatization is still important to improve selectivity of compound detection in a complex sample matrix as well as concentration detection limits. Very often, UV/vis detection of the chromophores does not give a satisfactory response owing to the very short light pathlength (50–100 μm) in CE. For example, the anticancer drug prospidin is a piperazinium derivative with chloroxypropyl groups but no UV/vis chromophore. Derivatization with diethyldithioccarbamate at 37 °C for 90 min in a basic solution, with loss of HCl, generates a product that absorbs light at 254 nm. Separation of the desired product from excess derivatizing agent is possible in 10 min by CE with a detection limit of 1 ng L^{-1}.[335]

Rimantadine is a synthetic analog of amantadine. Both are antiviral agents used for prophylaxis and treatment of influenza A. Because rimantadine is almost transparent in the UV/vis range, either indirect detection or derivatization has to be used to identify this compound. The indirect detection method used 5-mM 4-methylbenzylamine in 1 : 4 methanol–water as the absorbing background electrolyte for detection at 210 nm. The derivatization method used rimantadine to react with 1,2-naphthoquinone-4-sulfonic acid in an alkaline medium. CE determination of the derivative at 280 nm was performed in an uncoated capillary (44 cm × 75 − μm i.d.) using a 40-mM tetraborate buffer at pH 9.2. The detection limits were 0.1 and 2 mg L^{-1} for indirect detection and derivatization methods respectively. The methods were used to determine rimantadine in pharmaceutical products and for dissolution testing of Flumadin tablets.[336]

Most of the naturally occurring amino acids do not have proper UV/vis chromophores for CE analysis. Derivatization is a necessity for the determination of amino acids at reasonable concentrations. By using dansyl chloride to derivatize the amino acids, the enantiomeric forms of novel depsipeptide antitumor antibiotic BMY-45012, and its analogs, were determined by CE with UV/vis detection.[337] The compounds were subjected to total hydrolysis in a vacuum hydrolysis tube with 6-M HCl at 110 °C for 24 h. The hydrolyzed residue (about 7.8 mg) was dissolved in a water–acetonitrile solvent. For subsequent derivatization, the solution was further diluted to about 1.7 mg mL^{-1} with water. Dansyl chloride dissolved in acetonitrile (3.0 mg mL^{-1}) was utilized for the derivatization of standard native amino acids and those present in the hydrolyzate. A 50-μL sample solution was mixed with 50 μL of dansyl chloride solution and an aliquot of borate buffer at pH 9.08. The mixture was held at room temperature for 2 h and used directly for injection. The differing interaction of dansyl amino acids with amino-β-cyclodextrin copper complexes in the CE running electrolyte was the basis of the chiral separation of selected dansyl amino acids.[338] The reagent phanquinone (4,7-phenanthroline-5,6-dione) was applied as a prederivatizing agent for amino acids down to the sub micromolar level followed by micellar electrokinetic chromatography (MEKC) with detection at 240 nm.[339]

Examples of other derivatization approaches for amine-containing drugs follow. Ofloxacin acyl chloride was used to modify a wide variety of drugs such as amantadine, transexamic acid, and two amino acids

(glycine and methionine) into derivatives that could be detected at 300 nm.[340] The same derivatizing agent has been applied for the determination of gabapentin and vigabatrin at the 5-μM level.[341] The OPA-3-mercaptopropionic acid derivative of tobramycin could be detected at 230 nm down to 0.1 mg L^{-1}.[342] Chiral separation using β-cyclodextrin of aspartic acid enantiomers derivatized on-line by flow injection with OPA and mercaptoethanol was possible using MEKC.[343] Resolution of five β-blocker drugs, propranolol, oxprenolol, pindolo, metoprolol, and atenolol, after prederivatization with (+)-1-(9-fluorenyl)ethylchloroformate by capillary electrochromatography with a C_{18} column was directed toward determination of their enantiomeric composition.[344]

Relative binding of glycopeptides teicoplanin and ristocetin with alanine terminus peptides before and after reaction with acetic or succinic anhydride was an example of affinity CE.[345] All binding reactions were done on-line in the capillary with the glycopeptides reacting first with the anhydride and then with varying amounts of the alanine terminus peptides. It was ascertained how the modification of drugs can alter their affinities for target molecules.

The aminocychitol antibiotic amikacin can be derivatized with 1-methoxycarbonylindolizine-3,5-dicarbaldehyde at room temperature for 15 min before determination in plasma by MEKC with UV detection at 280 nm and standard fluorescence detection (excitation at 414 nm, emission at 482 nm).[346] However, there was only a twofold gain in sensitivity on switching from UV to fluorescence detection of the amikacin derivative. If laser excitation can be used (as discussed in the next section), the gain in sensitivity should be significantly higher.

4.2 Derivatization for Fluorescence Detection

The principles of fluorescence and the prerequisites for a good fluorophore, including the potential of using diode lasers in combination with a labeling procedure, have been reviewed previously for CE.[330] LIF detection is now commercially available for CE, and more industrial scientists are using LIF detection to detect trace amounts of analytes in complex matrices. LIF detection has several advantages. First, it offers excellent sensitivity;: under optimized conditions, a level of 10^{-10} M is feasible.[347] This is critical to pharmaceutical applications because sensitivity is often the most important parameter to consider when analyzing biological samples. Second, LIF offers a certain selectivity because, unlike UV absorbance, LIF selectively detects compounds that are fluorescent at certain wavelengths, and most organic compounds do not fluoresce. On the other hand, the fact that most organic compounds do not fluoresce is also a major limitation of LIF detection. Since the available excitation wavelengths of various lasers are limited, usually in the visible range, derivatization is often required when using CE with LIF detection. The following examples demonstrate the applicability of derivatization in CE with LIF detection for pharmaceutical analysis.

Sulfur compounds can be converted to fluorescent derivatives through several different reactions. Captopril, an antihypertensive agent, was derivatized through the thiol group with a dicarbocyamine label to give a fluorescent derivative with a wavelength maximum at 675 nm.[348] This wavelength was compatible with a semiconductor laser at 670 nm, which was used for LIF detection in conjunction with CE. Using a methanol-borate running electrolyte, CE also separated other labeled thiols such as cysteine and reduced glutathione from derivatized captopril (Figure 15). The detection limit of 2.5×10^{-8} M for captopril is limited by dilution due to the derivatization reaction. Thiouracil and phenyluracil were derivatized with 5-iodofluorescein before CE separation and LIF detection in the attomole range.[349] Determination of *S*-adenosyl-L-homocysteine and *S*-adenosyl-L-methionine

Figure 15 Electropherogram of a number of thiols labeled with CY5.3a.IA: (1) unreacted label; (2) captopril; (3) DL-homocysteine; (4) L-cysteine; (5) 3-mercaptopropionic acid; (6) 2-mercaptoacetic acid; and (7) reduced glutathione. (Reproduced with permission from Ref. 334.)

after chloroacetaldehyde derivatization was possible by capillary electrophoresis/laser induced fluorescence (CE/LIF) in less than 1 min.[350]

Drugs with active oxygen groups such as profens, including pranoprofen, fenoprofen, flurbiprofen, ketoprofen, and ibuprofen, can be derivatized using a water-soluble benzofurazan fluorescent reagent at room temperature using a triphenyl phosphine, diphenyl sulfide catalyst.[351] β-Cyclodextrin was added to the running electrolyte to facilitate the separation in a 50 cm $\times$ 50 μM i.d. capillary. With excitation at 488 nm and emission at 50 nm, CE/LIF detection limits of 0.16–0.3 fmol were attained.

Amines can easily be derivatized with a variety of reagents that generally have optimum excitation wavelengths in the 450–500 nm region, providing compatibility with the commercial 488-nm LIF laser. Huperzine was derivatized using rhodamine B isothiocyanate, and a CE/LIF detection limit of 4 nM was found.[352] Amino acids such as glycine, lysine, and glutamic acid were derivatized on-capillary with 3-(2-furoyl)quinoline-2-caboxaldehyde and detected by LIF at the 20–50-nM level.[353] Using native fluorescence, alkaloids such as normorphine, morphine, 6-acetyl morphine, and codeine could only be detected at the 200 ng mL^{-1} level after CE separation.[353] The same alkaloid mixture after N-demethylation with 1-chloroethyl chloroformate and then derivatization with FITC could be determined by CE/LIF at the 50–100 pg mL^{-1} level. The determination of FITC-derivatized amphetamine, methamphetamine, 3,4-methylenedioxymethamphetamine, and β-phenylethylamine in human urine by CE with or without dodecyl sulfate micelles using chip-based and fused-silica capillary instrumentation with LIF detection has been reported.[354] The results obtained via direct labeling of fortified urine were compared with those generated after FITC labeling of urinary extracts that were prepared by SPE. Using 5 mL of urine with a ''spiked amine'' to FITC ratio of 1 : 250, the SPE extract had a sensitivity of 200 ng mL^{-1} urine. That value is relevant for toxicology drug screening and confirmation. In contrast, with direct labeling of 10 μL of urine that had been alkalinized and diluted for derivatization, the limit of identification was 10 μg mL^{-1}, a value that is too high for practical purposes. Compared to fused-silica capillaries, electrophoresis in microstructures is shown to provide faster separation and higher efficiencies without loss of accuracy and precision.

4.3 Special Applications

4.3.1 Chiral Confirmation

With proper derivatization, CE has been used for the chiral separation of enantiomeric forms of derivatized amino acids. Liu et al. reported the determination of enantiomeric forms of amino acids derived from the novel depsipeptide antitumor antibiotic BMY-45012, and its analogs, the proposed structures shown in Scheme 1.[337] Amino acids were analyzed by complete hydrolysis and the hydrolyzate was derivatized with either dansyl chloride for UV absorbance detection or FITC for LIF detection in CE. For fluorescence detection, the fluorogenic reagent FITC was dissolved in acetone (0.01 M) as a stock solution. Amino acids were derivatized with FITC-derivatizing solution (5.0×10^{-4} M) under basic conditions (borate buffer, pH 9.08). The reaction

(**1**)

Compound	R_1	R_2
BMY45012	$CH(CH_3)_2$	$CH(CH_3)_2$
Analog-G439B	CH_2CH_3	CH_2CH_3
Analog-G451	$C(CH_3)_3$	$C(CH_3)_3$
Analog-G435	$C(CH_3)_3$	$CH(CH_3)_2$
Analog-G439A	$CH(CH_3)_2$	CH_3

was allowed to proceed for 2–4 h in the dark at room temperature and then stored at −20 °C prior to use. Both a metal chelate chiral CE method and a cyclodextrin-mediated host–guest interaction approach in MEKC with LIF detection confirmed the presence of several chiral amino acids, such as D-serine and L-β-hydroxyl-*N*-methylvaline, and the nonchiral amino acid sarcosine in the proposed structure. These methodologies provide a quick and sensitive approach for the determination of amino acid racemization in pharmaceutical natural products and have proved to be useful for structural elucidation refinement.

4.3.2 Oligosaccharide Determination

The derivatization of the pseudo-oligosaccharide acarbose (**2**) and its main metabolite **3** with 7-aminonaphthalene-1,3-disulfonic acid (ANDS) (Scheme 2) in human urine allowed the on-column LIF detection of the pseudo-oligosaccharides in human urine in the nanomolar range.[355] Before derivatization, 0.5-mL samples of urine or spiked urine were evaporated to dryness. A 100 µL volume of 0.08-M ANDS solution in acetic acid–water (3 : 17 v/v) and a 50 µL volume of 0.9-M $NaCNBH_3$ solution in dimethyl sulfoxide (DMSO) were added to each sample residue. The reagent solutions were freshly prepared before derivatization. The reaction tubes were vortex mixed and then incubated overnight at 40 °C. The efficient separation of these derivatives by CE using 100-mM triethylammonium phosphate buffer at pH 1.5 allowed the quantitation of acarbose and **3** in human urine after application of 300 mg of acarbose.

Assessment of the carbohydrate chains in glycoproteins is important for the quality control of such therapeutic antibodies.[356] After release of the four major carbohydrates by glycoamidase, derivatives were formed with 3-aminobenzoic acid and then separated by CE with LIF detection. Good precision in migration times and relative peak areas was found.

Both on-line and off-line capillary electrophoresis/mass spectrometry (CE/MS) trends for the determination of carbohydrates have been reviewed, showing the on-line sheath liquid interface with electrospray ionization (ESI) and ion trap MS detection is the most common instrumental mode.[357] Applications include oligosaccharides from pathogens, carbohydrate-based drugs and metabolites, and characterization of glycans from glycoproteins. It was noted that prior derivatization of neutral carbohydrates to make them charged would likely improve both the CE separation and sensitivity of MS detection.

4.3.3 Derivatization of Protein Samples

With the increased interest in the therapeutic use of the recombinant monoclonal antibody (rMAb) technique, a generic analytical approach for the analysis of size-based rMAb variants is desired. CE/LIF with proper derivatization has been shown to be promising as a

general method. The rMAb can be derivatized with a neutral fluorophore, e.g. 5-carboxytetramethylrhodamine succinimidyl ester (5-TAMRSE) for CE/LIF analysis.[358] Samples containing 2.5 mg of rMAb were buffer exchanged into 800 μL of 0.1-M sodium hydrogencarbonate (pH 8.3) using a NAP-5 column. A 10 μL volume of 5-TAMRSE (1.4 mg mL^{-1}) dissolved in DMSO was then added to 190 μL of rMAb solution and the resultant mixture incubated for 2 h at 30 °C. After incubation, 190 μL of the antibody–dye conjugate was loaded on to a second NAP-5 column and collected in 700 μL of 0.1-M sodium hydrogencarbonate (pH 8.3). The labeled sample, after incubating with SDS, can be separated by CE using a hydrophilic polymer as a sieving matrix. Using these precolumn labeling conditions, the detection of rMAb at a low-nanomolar concentration (9 ng mL^{-1}) is obtained with no apparent decrease in resolution or changes to the distribution of rMAb analyte species in comparison with an unlabeled sample. This assay can be used for monitoring the consistency of the bulk manufacture of a protein pharmaceutical and in providing a size-based separation of product-related variants and also nonproduct impurities. The CE/LIF with derivatization demonstrated comparable resolution and sensitivity to silver-stained sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE) but offered the advantages of enhanced precision and robustness, speed, ease of use, and on-line detection.

CE was used for the study of palmitoyl derivatization of interferon-α_{2b} (p-IFN-α).[359] The derivative was prepared by covalent attachment of the fatty acid to lysine residues in the protein through a reaction with *N*-hydroxysuccinimide palmitate (NHSP) ester (Scheme 3). The first step involved the preparation of an intermediate NHSP, which in turn was reacted with IFN-α. CE was able to study the effect of reaction time and reagent/protein ratio.

Scheme 3. Synthetic process for the fatty acrylation of IFN-α. R–COOH palmitic acid. DCU-N,N′-dicyclohexylurea DCC-N,N′-dicyclohexylcarbodiimide (Reproduced with permission from Foldvari et al. (359).)

4.4 Derivatization Modes

In general, derivatization in CE can be accomplished by either pre- or postcolumn derivatization. The precolumn derivatization is similar to methods used for derivatization in HPLC. Since CE has a much superior separation power, the interference from the derivatization by-products may be less of a problem than in LC. However, CE is very sensitive to the ionic strength of the sample. Additional sample preparation may be needed if the mixture in the derivatization reaction has a high ionic strength.

Postcolumn detection strategies have also been developed for CE. An overview of the advantages and limitations of postcolumn derivatization for CE can be found.[330] The details about the instrumental developments and applications of postcolumn derivatization in CE can also be found in the literature.[331] Again, much of the same derivatization chemistry developed for HPLC is applicable to CE. One exception is postcolumn photolysis, perhaps due to the difficulty of modifying commercial instruments. Using a Teflon-coated UV transparent capillary and a Pen-Ray Hg UV lamp, an on-column photoreactor has been developed for CE and applied for the determination of phytosiderophores (iron containing species) and the nonprotein amino acid nicotianamine.[360] The relationship of irradiation window length and sensitivity was investigated, and both UV detection and contactless conductivity detection were used.

Various systems to merge the reagent solution with the separation medium have been developed, including coaxial capillary reactors, gap reactors, and free- solution or end-column systems. For all reactor types, the geometry of the system, and the method used to propel the reaction mixture (by pressure or by voltage) appear to be critical to preserve the separation efficiency. To minimize peak broadening, careful designing is necessary in terms of connecting a reagent capillary to form a tee. Because of the small (50–75 μm) i.d. of the capillaries used, normal mixing through a diffusion process is sufficient. The most frequently applied reactors are (i) coaxial, (ii) gap, (iii) free-solution, and (iv) sheath flow. With proper design, plate numbers of over 100 000 could be realized. The strict requirements on the reaction rate in postcolumn derivatization in CE limit the number of different reagents that have been used. For LIF detection, mainly OPA and its naphthalene analog have been used. With careful instrument design, the detection limits of postcolumn derivatization can be comparable to those of precolumn derivatization.

An example of postcolumn CL detection for CE is shown in Figure 16.[361] The CL reagent tris(bipyridyl) ruthenium(II) is added at 10 μL min^{-1} using a syringe pump through a capillary into a reaction tee where it is

Figure 16 Schematic representation of a cell for CE with postcapillary $Ru(bpy)_3^{3+}$ chemiluminescence detection. (Reproduced with permission from Ref. 361.)

oxidized to the +3 state at a Pt working electrode. The CE electric field has been decoupled from the potential applied to the Pt electrode by a CE capillary fracture that is covered by a Nafion tube. This $Ru(bpy)_3^{3+}$ reactant can undergo CL with CE-separated compounds such as aliphatic amines through detection of the visible light produced at the end of the reaction tube in front of the photomultiplier (PMT) detector. Amino acids proline, valine, and phenylalanine were separated with theoretical plate numbers of 74–84 000 and detection limits in the sub 1-μM range.

5 CONCLUSION

It can be argued that the advances made in MS detection for GC, HPLC, and CE have diminished the importance of chemical derivatization for these techniques. However, chemical derivatization of drugs is critical for GC because these samples, which often contain multiple polar substituents, are simply not volatile or thermally stable. MS detection for HPLC and CE is still expensive and requires considerable operator expertize. Chemical derivatization with HPLC to permit fluorescence detection is certainly one of the more desirable methods for routine use to solve selectivity and detectability problems for drug samples not amenable to GC. As the cost of laser technology comes down, the same statement will eventually be true for CE also. The use of inexpensive light-emitting diodes as fluorescent visible and UV sources for CE also is showing promise.

ABBREVIATIONS AND ACRONYMS

ANDS	7-Aminonaphthalene-1,3-disulfonic Acid
AUFS	Absorbance Units Full Scale

The preparation and evaluation of optically active compounds have become very important for the development of new drugs. The determination of chiral purity of drugs is essential in order to guarantee safety and effectiveness. Isomeric impurities may have unwanted toxicological, pharmacological, or other side-effects. Therefore we decided to prepare an article entitled ''Chiral purity in drug analysis''. This article is divided into five sections (introduction, production, regulation, evaluation methods and conclusion). In the introduction, the importance of assessing the isomeric impurities in drug analysis will be discussed. In the second section, production methods for optically active compounds, except the stereoselective synthesis method, will be summarized briefly. In particular, new trends in the production of chiral drugs, such as the simulated moving beds (SMB) method, will be described. In the third section, regulatory perspectives in the USA (Food and Drug Administration (FDA)), EC, and Japan will be described and some regulatory guidelines and guidances by, for example, the FDA, the Committee for Veterinary Medicinal Products (CVMP), and the International Conference on Harmonization (ICH) will be mentioned. In the fourth section, methods for the determination of stereoisomeric drugs will be summarized. Methods such as gas chromatography (GC), high-performance liquid chromatography (HPLC), and capillary electrophoresis (CE) have been summarized. The focus will be on direct evaluation methods, i.e. those using chiral stationary phases (CSPs). Practical details for testing a drug's optical purity are also given.

1 INTRODUCTION

The stereoisomers of a molecule have the same constitution in both molecular formula and atomic bonding, but differ in the spatial orientation of the atoms or groups of atoms within the molecule. Enantiomers are stereoisomers with the same molecular formula, but which differ in the spatial arrangement of atoms within the molecule. They are nonsuperimposable mirror images, and quite often differ in their pharmacological activity, either qualitatively or quantitatively. Usually, only one of the isomers fully contributes to the therapeutic action, and the other is often classified as ''isomeric ballast''.[1] In the racemic mixtures that are used the usefulness of kinetics is generally questionable. Exposure of patients to the ''isomeric ballast'' present in about 50% of the most commonly used drugs will probably remain for many decades. However, approximately 50% of all drugs in therapeutic use have a chiral center, and hence about 25% of chiral drugs have been marketed as the racemate,[2,3] because the choice between single stereoisomers (homochiral drugs) and composite chiral drugs (mixtures of stereoisomers) depends upon therapeutic advantages (such as a reduction in xenobiotic load), possible adverse side-effects, and development costs. Therefore, the preparation of enantiopure compounds has become very important in many branches of chemistry, and the evaluation of enantiopure compounds is required during the development of new drugs. Moreover, determination of the chiral purity of drugs is essential in order to guarantee safety and effectiveness. Isomeric impurities may have unwanted toxicological, pharmacological, or other side-effects. One enantiomer sometimes shows high toxicity while another is effective. Some examples of activity differences between enantiomers are noted in Table 1. As can be seen from the table, the production of enantiopure compounds, regulation of enantiopure compounds and evaluation methods for chiral drugs are very important in the development of new chirally active substances and products.

Table 1 Activity differences between enantiomers

Compounds	Activities of each enantiomer	Ref.
Acebutolol	Acebutolol, a β-blocking drug, is used in the treatment of hypertension and is marketed as a racemate. (*S*)-(−)-acebutolol is the eutomer.	4
Amphetamine	Amphetamine, an inhibitor of dopamine, is used clinically as a racemate, but (*S*)-(+)-amphetamine is four times as effective as its antipode.	5
Flurbiprofen	Both enantiomers possess analgesic activity and the drug is marketed as the racemate. (*S*)-(+)-flurbiprofen shows greater antiinflammatory activity.	6
Ketamine	The anesthetic potency of (*S*)-(+)-ketamine is found to be three times higher than that of (*R*)-(−)-ketamine.	7
Ketoprofen	Ketoprofen, a nonsteroidal anti-inflammatory drug, is marketed as the racemate, but only the *S*-enantiomer is pharmacologically active.	8
Levamisole	Levamisole is the (*S*)-(−)-isomer of tetramisole, and has effective anthelmintic activity; whereas the (*R*)-(+)-isomer, dexamisol, causes vomiting.	9
Naproxen	Except for naproxen, chiral nonsteroidal antiinflammatory drugs are marketed for clinical use as the racemate. However, in vitro studies have shown that the antiinflammatory activity exists almost solely in the (*S*)-enantiomer.	10
Propranolol	Propranolol, a β-adrenoceptor blocking drug, is administered as a racemate, but only (*S*)-(−)-propranolol possesses effective activity.	11
Propoxyphene	α-Dextropropoxyphene is marketed as an analgesic drug, whereas α-levopropoxyphene has no analgesic activity but is marketed as an antitussive agent. β-Dextro and β-levopropoxyphene are substantially inactive.	12
Salbutamol	Salbutamol, a β_2-adrenoceptor stimulant, is used clinically as the racemate. The activity resides predominantly in the (*R*)-(−)-enantiomer with little or no activity attributed to the (*S*)-(+)-enantiomer.	13
Sotalol	D-(+)-Sotalol possesses antiarrhythmic efficacy, whereas L-(−)-sotalol possesses β-adrenoceptor blocking activity.	14
Timolol	(*S*)-(−)-Timolol is one of the few β-adrenoceptor blocking drugs marketed as the pure enantiomer, whereas (*R*)-(+)-timolol is considerably less potent a β-adrenoceptor antagonist than (*S*)-(−)-timolol.	15
Verapamil	Verapamil is a calcium channel blocker with antiarrhythmic, antianginal, and antihypertensive properties as a racemate, but (−)-verapamil has more negative dromotropic activity than (+)-verapamil.	16
Warfarin	Warfarin, is a blood anticoagulant used clinically as a racemate. (*S*)-(−)-warfarin is five times as active as (*R*)-(+)-warfarin.	17

In this paper, production methods for optically active compounds, especially new trends, such as the SMB method are described. Regulatory perspectives which exist in the USA, EU and Japan are outlined, and some regulatory guidelines and guidances by, for example, the FDA and ICH are mentioned. Methods for the determination of stereoisomeric drugs, such as GC, HPLC, and CE, are summarized. The focus will be on the direct evaluation methods, i.e. those using CSPs. Practical details for testing the purity of a drug's enantiomers are also demonstrated.

2 PRODUCTION OF CHIRAL DRUGS

2.1 History

The need for separating enantiomers for pharmaceutical applications is increasing, as regulatory aspects become more stringent. It is well known that isomers can have different therapeutic values and therefore enantiomer separation is an important issue, particularly in health-related fields. During the past few decades there have been three principal methods for producing enantiopure compounds. The first method involves numerous synthetic strategies to prepare enantiopure building blocks, or chiral auxiliary reagents.[18,19] This approach is based on the development of optically active catalysts, which transfer their chiral information during the creation step of new centers of chirality. The second method involves the separation of enantiomers from racemic mixtures. One classical separation method for the preparation of enantiopure compounds is the recrystallization of diastereomeric salts.[20] However, this is not suitable for industrial scale-up and automation.[21] A third method uses conventional chromatographic techniques for the separation of enantiomers. This method is also difficult for scale-up because separation factors are low. Recently, much attention has been paid to continuous chromatography, particularly SMB technology because of its improved efficiency. Continuous chromatography in SMB eliminates the drawbacks of batch chromatography; namely, dilution of species and low utilization of

Figure 1 Concept of the simulated moving-bed adsorber system for optical resolution. (Reproduced from Negawa and Shoji,[25] with permission from Elsevier Science.)

adsorbents. As a production method for enantiopure compounds, SMB is described in more detail in section 2.2.

2.2 Simulated Moving Beds Technology

The concept of SMB technology has been known since 1961, when the first patent by Broughton from Universal Oil Products (UOP, Des Plaines, IL, USA) described the separation of structurally related hydrocarbons.[22–24] The principle of SMB technology is a rotary valve, which periodically changes the position of feed, eluent, extract and raffinate lines along the bed. Negawa & Shoji[25] reported the concept of the SMB system, as shown in Figure 1; that is, a situation where the stationary phase is moving, but in the real equipment the feed line, desorbent feed line, raffinate line and extract lines move intermittently.

It has been shown[26–29] that this can be accomplished in units consisting of a set of fixed bed chromatography columns arranged in a similar manner to that illustrated in Figure 2 (boxes 1–12), where the periodic movement of inlet and outlet ports is in the same direction as the fluid flow. In Figure 2 the binary mixture (A + B) to be separated constitutes the feed stream to the unit. The more adsorbable component, A, is collected in the extract stream, whereas the less adsorbable one, B, is collected in the raffinate stream. Each section of the unit plays a specific role in the operation. Section 1 (boxes 1–5) lies between the desorbent inlet port and the extract port; section 2 (box 6) lies between the extract port and the feed inlet port; section 3 (boxes 7–9) lies between the feed inlet port and the raffinate outlet port; section 4

Figure 2 Scheme of a four-section simulated moving bed unit for continuous adsorptive separations with port distribution 5-1-3-3. (Reproduced from Mazzotti et al.,[27] with permission from Elsevier Science.)

(boxes 10–12) lies between the raffinate outlet port and the desorbent inlet port. Separation is performed in the two central sections. Component B is carried by the mobile phase, while component A is retained by the stationary phase. The eluent (D), is used to desorb component A from the first section, in order to regenerate the adsorbent. Finally, component B is adsorbed in the

fourth section of the unit, to regenerate the desorbent itself.

2.3 Application of Simulated Moving Beds Technology to Chiral Drug Substances

SMB technology is useful for separating large amounts of compounds as it is a continuous separation process. It has found new applications in the areas of biotechnology, pharmaceuticals and fine chemistry. Pilot and industrial SMB for such applications have been developed by UOP and Separex.[30] Scaling down of the Sorbex flowsheet becomes less economical than using a system of individual beds segmented by valves and feed and product lines. Therefore, there is a growing demand in the pharmaceutical industry for efficient and cost effective methods for purifying optical isomers. More recent applications are related to chiral technology.[31–42] More than 98.0% enantiomeric excess has been obtained by using polysaccharide-type CSPs. One of these compounds, NK-104 (Nissan Chemical Industries Ltd., Tokyo, Japan), which is a synthetic hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitor, will be the first enantiopure drug produced by SMB technology in the near future.[34] Examples of enantiopure drugs produced by using SMB are summarized in Table 2. Recently, new applications of SMB chiral separation by using the GC[43] and supercritical fluid chromatography[44] have been published. In elution chromatography, high purity and high recovery cannot be achieved with low resolution. However, SMB chromatography, as a manufacturing process step, is a cost-effective method for producing chiral drugs.

3 REGULATION OF CHIRAL DRUGS

3.1 International Conference on Harmonization

In recent years, the regulatory authorities and industry associations set-up to promote international harmonization of regulatory requirements have undertaken many important initiatives. Regulatory guidance on the nature and extent of investigations into the properties of chirally active substances is required, in order that the production and marketing of compounds with adverse effects can be avoided. One of the goals of harmonization is to identify and reduce differences in the technical requirements for drug development among regulatory agencies.[45]

Six groups (Table 3), which represent the regulatory bodies and research-based industries in the EU, Japan and the USA, organize the ICH, and discuss harmonization of the technical requirements for registration of pharmaceutical products in these regions. Most new drugs and medicines are developed in the EU, Japan and the USA, and therefore when the technical requirements are agreed, new drugs can be developed and marketed without delay in these three regions. Moreover, the ICH steering committee includes representatives from each ICH sponsor and the IFPMA, as well as observers

Table 3 The founder members of the ICH

Region	Regulatory body	Research-based industry
Europe	EC (European Commission)	EFPIA (European Federation of Pharmaceutical Industries' Associations)
USA	FDA	PhRMA (Pharmaceutical Research and Manufacturers of America)
Japan	MHW (Ministry of Health and Welfare, Japan)	JPMA (Japan Pharmaceutical Manufacturers Association)
Observers	WHO Representatives of EFTA Canada Health Protection Branch	
ICH steering committee	IFPMA	

WHO, World Health Organization; EFTA, European Free Trade Association; IFPMA, International Federation of Pharmaceutical Manufacturers Association.

from the WHO, the Canada Health Protection Branch, and the EFTA. The ICH is a joint initiative, involving regulators and industry as equal partners in the scientific and technical discussions of the testing procedures required to ensure and assess the safety, quality and efficacy of medicines. Regulatory perspectives of the ICH are explained in detail in some regulatory guidelines and guidance.

3.2 Impurities in New Drug Substances and Products

The nature and concentration of impurities in new drug substances produced by chemical synthesis are regulated by the ICH guidelines "*Impurities in New Drug Substances*" (Topics Q3A)[46] and "*Impurities in New Drug Products*" (Topics Q3B),[47] which deal with chemical and safety aspects. Classification and identification of impurities are included in chemical aspects. Threshold limits for drug impurities should depend on each individual drug and be based on scientific rationale. The structures of impurities that occur at concentrations of 0.1%, or greater have to be determined. New drugs used for preclinical and/or clinical studies can have impurities. If the proposed concentration of an impurity is not specified, the safety of that impurity has to be studied according to the threshold limits given in Table 4. Although impurities in new drug substances and products are regulated, the guidelines do not apply to enantiomeric impurities in new chiral drugs, even though enantiomeric impurities may be regarded as conventional impurities.

Table 4 The qualification threshold

Maximum daily dose	Qualification threshold
Not more than 2 g	0.1%, or 1 mg per day, intake (whichever is lower)
More than 2 g	0.05%

3.3 Guidance for Chiral Active Substances

The FDA's policy statement for the development of new stereoisomeric drugs was issued in 1992.[48] Later, a *Note for Guidance on the Investigation of Chiral Active Substances* was approved in June 1997 by the CVMP. This "Note" is valid from January 1, 1998.[49] According to the "Note", the identity and stereoisomeric purity of the active substance, its optical rotation (OR), melting point, and characteristics when undergoing liquid chromatography using a CSP have to be studied.

However, chiral impurities of new optically active drug substances are excluded from the ICH Guidelines[46,47] because of practical difficulties in quantifying them and identifying the given thresholds. Chiral impurities in chiral new drug substances and new drug products should be treated according to a decision tree, as outlined in Figure 3, and the ICH Guidelines "*Test for new drug substances that are optically active*" (Table 5) (Topics Q6A).[50] At present, the concentration of the antipode, that is, the chiral impurity of chiral drugs, is not regulated in Topics Q6A, but, ideally, the antipode should be regulated as an impurity. As described in Table 4, if the toxicity of the antipode is unclear, methods have to be available which will detect 0.05% chiral impurity.

4 EVALUATION METHODS FOR CHIRAL DRUGS

Over the last two decades, chiral analytical technology and chiral purity in drug analysis have acquired increasing prominence, because various aspects of pharmaceutical activity, such as pharmacology, drug quality control, toxicology, require these analysis. For these purposes, powerful and widely applicable analytical tools are needed to determine the enantiomeric purity of chiral drugs. Chromatographic methods using GC, HPLC, and electrophoretic methods such as CE have been developed.

* Chiral substances of natural origin are not addressed in this Guidance.

† As with other impurities arising in and from raw materials used in the synthesis of drug substances control of chiral quality could be established alternatively by applying limits to appropriate starting material or intermediates when justified from development studies. This will be essentially the case when there are multiple chiral centers (e.g. three or more), or when measurement in drug substance at an appropriate sensitivity is technically impossible.

‡ A chiral assay may be necessary if chiral impurity testing is done via a method which is equivalent to an assay procedure.

Figure 3 Decision tree to establish the identity, assay and chiral impurities procedures in a new drug product containing a chiral drug substance.

Table 5 Tests for new drug substances and products that are optically active

	Drug substance	Drug product
Impurity or degradation product	Impurities: for chiral drug substances that are developed as a single enantiomer, control of the other enantiomer should be considered in the same manner as for other impurities. However, technical limitations may preclude the same limits of determination or qualification being applied. If it is technically difficult to effect control in the drug substance itself, assurance of control could be given by appropriate testing of a starting material or intermediate, with suitable justification.	Degradation products: control of the other enantiomer in a drug product is necessary if that enantiomer has been shown to be a degradation product.
Assay	An enantioselective determination of the drug substance should be part of the specification. It is considered acceptable for this to be achieved either through use of a chiral assay procedure or by the combination of an achiral assay together with appropriate methods of controlling the enantiomeric impurity.	Where development studies have demonstrated that the enantiomer is not a degradation product, an achiral assay may be sufficient. However, a chiral assay is preferred or, alternatively, the combination of an achiral assay plus a procedure to control the presence of the opposite enantiomer.
Identity	The identity test(s) should be capable of distinguishing a single enantiomer from its opposite enantiomer. Where a drug substance is a racemate, the identity method should be capable of verifying the racemic nature and distinguishing it from either enantiomer.	An identity test should be established that is capable of verifying the presence of the correct enantiomer or the racemate, as appropriate.

In principle, there are three methods of separating enantiomers: (1) by using enantiopure derivatizing reagents to convert enantiomers to diastereomers, which can then be separated on an achiral column; (2) by using chiral mobile phases (except GC); and (3) by using CSPs.

4.1 Gas Chromatography

The first CSP for separating enantiomers by GC was synthesized in 1977 by coupling polysiloxane and L-valine-*tert*-butylamide, which is now available commercially as Chirasil-Val (Chrompack, Middelburg, The Netherlands). Separation of 11 mixtures of alcohol enantiomers, as isopropyl urethane derivatives, by Chirasil-Val is shown in Figure 4. The separation was completed within 40 min.[51] Separation of the enantiomers of sulfur compounds[52] was also successful within 30 min. Saeed et al.[53] and König et al.[54] synthesized chiral polysiloxane attached to either L-valine-*tert*-butylamide or L-valine-(*S* or *R*)-phenylethylamide as a chiral moiety. Fused-silica capillary columns coated with various CDs linked to the polymer have also been developed. Chirasil-Dex, where the β-CD was linked to the polymer through only one 6-*O*-octamethylene spacing group, was introduced by Jung & Schurig,[55] and is now available commercially. A summary of recently developed, commercially available CSPs is given in Table 6. The advantages of GC for the separation of enantiomers are the high efficiency, sensitivity, and speed of chiral separation. The disadvantages are that the volatility, thermal stability and resolvability of the analyte limit the usefulness of the technique.[56] However, GC is useful for separating enantiomers of nonaromatic ring compounds, which cannot be detected by the systems used with HPLC.

4.2 High-performance Liquid Chromatography

4.2.1 Chiral Derivatization

Approximately 30% of chiral compounds have been analyzed by indirect methods, because they could not be separated by using CSPs. The indirect method is based on the reaction of a racemic mixture with a chiral reagent to form a pair of diastereomers, which possess different physicochemical properties and hence can be separated by an achiral column. The acid chloride of (*S*)-(−)-*N*-trifluoroacetylproline is a widely used derivatizing agent[57] and has been used for resolving racemic amines and alcohols by normal-phase chromatography. (*S*)-(−)-*N*-1-(2-naphthylsulfonyl)-2-pyrrolidine carbonyl chloride (NSP-Cl),[58] a derivatizing reagent for primary or secondary amines and alcohols, has been successfully used for determining the enantiomeric purity of diltiazem hydrochloride (a Ca^{2+} channel blocker),[59] and enprostil (an anti-ulcer drug). The derivatized enantiomers were separated by normal-phase chromatography. 2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyl isothiocyanate (GITC), which was developed by Kinoshita et al.[60] and Nimura et al.[61] as a derivatizing reagent for an amino group, has also been successfully used in reversed-phase HPLC for determining the enantiomeric purity of denopamine,[62] etilefrine, phenylephrine and trimetoquinol hydrochloride. 1-(9-Fluorenyl)ethyl chloroformate (FLEC) has been widely used for the diastereomeric derivatization of primary or secondary amines and alcohols.[63] For carboxylic acids, or their derivatives, of biological interest, separation of enantiomers can be achieved by using reversed-phase HPLC with an ODS column, after derivatization with alanine-β-naphthylamide. This method was used by Kagawa et al.[64] to determine the enantiomeric purity of acetyl-L-carnitine, which may be important as it can stimulate actions of learning behavior and can be used as a drug. Typical chromatograms are shown in Figure 5.

4.2.2 Chiral Stationary Phases

Direct methods using CSPs have been used extensively because CSPs based on amino acid derivatives,[65–68] cellulose,[69–71] CDs,[72–74] ovomucoid,[75,76] bovine serum albumin,[77] crown ethers,[78,79] and antibiotics (Figure 6)[80–85] are now available commercially (Table 7).

Recently, in the development of new chiral drugs, most determinations of chiral purity in drug analysis have been performed by using CSPs. For example, in our laboratory, direct separation of the enantiomers of diltiazem hydrochloride, which was previously achieved by derivatization with NSP-Cl,[58] was achieved by using

ovomucoid CSP, where protein is embedded on a silica-gel matrix.[86,87] With this method, good linearity between the peak area and the amount of sample used permitted determination of the enantiomeric purity of the antipode at levels down to about 0.1%. In 1994, direct separation of the enantiomers of imidapril hydrochloride, which previously required chiral derivatization, was achieved by using the CSP Chiralpak WH, a ligand-exchange type column where Cu^{2+} is used as a mobile phase additive.[88] With this method, good linearity between the peak area and the amount of sample used, combined with a signal-to-noise ratio of 3, gave a detection limit of about 0.2% for the antipode. In our laboratory approximately 70% of chiral separations of drugs have been achieved by using CSPs.

Dolezalova & Tkaczykova[89] reported the enantiomeric purity of levodopa and carbidopa (L-DOPA and L-CDOPA, respectively, both of which are used for the treatment of Parkinson's disease), and methyldopa (L-MDOPA, used as an antihypertensive) by using Chirobiotic T, in which teicoplanin is used as a chiral moiety. The detection limits of the antipode on L-DOPA, L-MDOPA and L-CDOPA were 0.03%, 0.3% and 0.4%, respectively. Torrens et al.[90] reported the enantiomeric

Figure 5 Enantiomeric purity testing of acetyl-L-carnitine. (Reproduced from Kagawa et al.,[64] with permission from Elsevier Science.)

purity of cizolirtine, a potent analgesic that is currently in phase II clinical trials, by three independent methods, namely, ^{1}H-NMR (nuclear magnetic resonance), CE (using β-CDs as chiral resolving agents) and HPLC (using a Chiral AGP column). Typical chromatograms are shown in Figure 7. The detection limits of the antipode obtained by the three methods were: 1% with ^{1}H-NMR, and 0.5% with either HPLC or CE.

Despite the numerous CSPs now available commercially, much research is still carried out to develop novel CSPs that have wider or more specialized enantioselectivity. Pirkle & Terfloth[91] developed a new CSP derived from *S*-naproxen as the chiral moiety. Haginaka et al.[92] investigated the separation of enantiomers on a CSP based on ovoglycoprotein and the effect of aggregation of ovoglycoprotein. 18-Crown-6-tetracarboxylic acid, which has a high enantioselectivity for primary amino compounds, has been immobilized to silica gel as the chiral selector.[93–95]

In addition to the development of CSPs, some applications for mobile phase additives have also been published. Separation of the enantiomers of hydrophobic amino compounds by using Crownpak CR(+), dynamically coated chiral crown ether as chiral moiety, has been studied.[96] Here, the enantiomeric hydrophobic amino compounds were easily eluted and successfully separated by the addition of β-CD (an inclusion reagent) and/or various salts. Typical chromatograms are shown in Figure 8.

Novel detectors for the stereospecific analysis of chiral drugs in plasma have been developed and investigated. In 1999, Kanazawa et al.[97] reported the separation of enantiomers of lorazepam, ibuprofen and flubiprofen on Chiralcel OD, using UV, circular dichroism and OR detection systems. Typical chromatograms of ibuprofen are shown in Figure 9. Chiroptical detection systems, such as circular dichroism and OR, are useful for pharmacokinetic studies of chiral drugs in biological samples, because the front peak and other peaks having no chirality are not detected by these methods.

For future CSPs, molecular imprinting (MI) technology is likely to be introduced. The technique of MI is shown schematically in Figure 10.[98,99] The selected analyte or

template molecules is first allowed to establish binding interactions with polymerizable chemical functionalities, that is, hydrogen bonds, ion pairing, $\pi-\pi$ interaction or hydrophobic-effect-driven reactions, and the resulting complexes or adducts are subsequently copolymerized with crosslinkers into a rigid polymer. After the template molecules are extracted, specific recognition sites are left in the polymer in which the spatial arrangement of the functional groups in the polymer network, together with the shape, are complementary to the imprinted molecule. Therefore, an MI polymer appears to have the potential for chiral recognition, and an analytical method using an MI polymer will be a powerful tool for chiral separation of drugs.

4.3 Capillary Electrophoresis

CE is another powerful method for separating enantiomers.[100–103] Relatively fast separation, with high resolution, can be achieved with one capillary tube, without a special chiral column or an organic solvent. Furthermore, CE has many attractive features, such as the speed of method development and analysis, robustness, simplicity and cost. The separation solution can easily be altered to find the optimum separation media, and an expensive chiral selector can be used because only small amounts of media are required. Among various different CE modes, both capillary zone electrophoresis (CZE) and electrokinetic chromatography (EKC), in which only a chiral selector is added to the usual running buffer solution, are most widely used for enantiomer separations.[100,101] EKC, where an ionic pseudo-stationary phase is employed, is one branch of the CE techniques and has the capability to separate electrically neutral analytes. Various ionic additives or aggregates, such as micelles, microemulsions, and vesicles have been used as a pseudo-stationary phase in EKC. Among them, EKC using micelles, i.e. micellar EKC (MEKC) has become most popular.[104,105] Normally, an ionic surfactant (e.g. sodium dodecyl sulfate, SDS; or bile salts) solution is used as a running buffer solution in MEKC.

Typically, for the enantiomer separation of ionic analytes, neutral chiral selectors are employed in the CZE mode. CDs and their various derivatives have been

Figure 10 Schematic representation of imprint formation following the self-assembly approach. (Reproduced from Ramström and Ansell,[98] with permission from John Wiley & Sons Limited.)

found to be most effective in CZE for a wide range of drugs.[106,107] On the other hand, charged pseudostationary phases having chirality are added to the running buffer solution in EKC. Therefore, EKC enantiomer separation can be applied to both ionic and nonionic analytes. CDs are also effective chiral selectors in the MEKC mode.[101,104] This mode is called CD modified MEKC (CD/MEKC). CDs, polysaccharides, proteins,

crown ethers, and chiral surfactants, which are also effective chiral moieties in HPLC have been found to be useful in CE for the separation of enantiomers. Typical chiral selectors that have been successfully employed for the CE enantiomer separations are shown in Figure 11.

4.3.1 Use of Cyclodextrins and Crown Ethers

Among the various chiral selectors used in CE for separation of enantiomers, CDs have attained the greatest popularity, because they are capable of recognizing a wide range of enantiomers. When neutral CDs are used, the separation mode is called CD/CZE, and enantiomers of basic and acidic drugs can be separated. One example is shown in Figure 12, where ropivacaine and its enantiomer (R-form), and other related derivatives (enantiomers) have been successfully separated by CD/CZE. The running buffer was 0.1 M phosphoric acid, pH 3.0 (adjusted by triethanolamine), containing 10 mM 2,6-dimethyl (DM)-β-CD.[108] Detection was at 206 nm. The method also detected the required 0.1% of enantiomeric impurity, and proved to be robust. Some of these CE enantiomer purity testings have been accepted as a part of regulatory submissions or submitted to the FDA or the pharmacopoeias. Enantiomers of various ionic drugs have been successfully separated by this CD/CZE mode, using one of these CD derivatives.[106,107]

Recently, CE enantiomer separations by the combination of neutral CDs and other additives, such as surfactants (CD/MEKC mode),[109] charged CDs (dual CD system),[110,111] and crown ethers,[112] have been demonstrated. By combining CDs with another additive that can interact with the analytes, enantioselectivity has been much improved. For example, the enantiomers of 1-aminoindan, could not be separated by CZE with either 18-crown-6 or DM-β-CD, but were successfully separated by CZE using 5 mM 18-crown-6 and 5 mM DM-β-CD. Enantiomers of some other aminocompounds, such as 1,2,3,4-tetrahydro-1-naphthylamine, and 1-methyl-3-phenylpropylamine, have also been successfully separated by a dual system using CDs and crown ethers.[112]

Charged CDs have also been successfully used alone (CD/EKC) or with other additives, such as neutral CDs (dual CD system). Various anionic CD derivatives, such as sulfobutyl ether-, phosphated-, sulfated-, or carboxymethylated-, are now available commercially.[113] Positively charged CD derivatives, such as 2-hydroxypropyltrimethylammonium β-CD, heptamethylamino- and 6^A-methylamino-β-CD, have been synthesized and used in CE for separation of enantiomers.[114] Enantiomers of acidic pharmaceuticals that have a carboxylic group, such as nonsteroidal anti-inflammatory agents (e.g. ibuprofen, naproxen, ketoprofen) have been successfully separated by using these cationic CD derivatives, that is, by the CD/EKC mode.

Bile salt	R_1	R_2	R_3	R_4
SC	OH	OH	OH	ONa
STC	OH	OH	OH	$NHCH_2CH_2SO_3Na$
SDC	OH	H	OH	ONa

Proteins used for separation of enantiomers

Protein	Molecular mass	pI	Carbohydrate (%)
BSA	67 000	4.7	–
HSA	68 000	4.7	–
Fungal cellulase	60 000–70 000	3.9	6
Cellobiohydrolase I	60 000–70 000	3.9	6
α_1-AGP	44 000	2.7	45
Avidin	70 000	10	20.5
OVM	28 000	4.5	30
Conalbumin	77 000–87 000	6.0–6.8	–
Casein(α-casein)	26 200	4.7	–
Ovoglycoprotein	25 000	3.9	20

Figure 11 (*Continued*)

It is often difficult to control the position and the number of the substituents in these synthesized CD derivatives. The substitution distribution significantly influences the enantioselectivity. One example is the separation of enantiomers of denopamine and trimetoquinol by CZE with DM-β-CD.[115] Resolution values obtained from six different commercial DM-β-CD were different and showed that the degree of methyl substitution probably differed. This was confirmed by HPLC purity testing and matrix-assisted laser desorption ionization/time-of-flight mass spectrometry (MALDI/TOFMS) analysis. To overcome these problems, single-isomer sulfated CDs have been developed recently.[116] Various enantiomers were successfully separated, as in the randomly derivatized charged CDs. Reproducibility in the enantioselectivity will be controlled by using these single-isomer derivatives.

The chiral crown ether, 18-crown-6-tetracarboxylic acid, has been shown to be effective for the separation of chiral amino drugs.[117] Compared with the results obtained by HPLC with a commercially available chiral crown ether column (Crownpak CR(+)), CE with 18-crown-6-tetracarboxylic acid was effective for the separation of enantiomers where the amine functional group and the stereogenic center is long. In a nonaqueous CE mode with formamide, enantiomer separation of 1-phenylethylamine, which has not been separated by any other mode of CE, was achieved by adding the tetra-*n*-butylammonium salt to the running buffer containing 18-crown-6-tetracarboxylic acid.[118] It is expected that various chiral crown ethers that can be applied in the CE system will be developed, because, at present, only 18-crown-6-tetracarboxylic acid is available commercially.

4.3.2 Use of Polysaccharides, Antibiotics and Proteins

Polysaccharides, antibiotics, and proteins have been successfully used in CE for separation of enantiomers. Polysaccharides, such as chondroitin sulfates, dextran

Figure 12 Enantiomer purity testing of ropivacaine (4*S*-form) by CZE using DM-β-CD. (a) Separation of related enantiomers including the ropivacaine minor enantiomer (4*R*-form); and (b) detection limit (0.1%) of the minor enantiomer. Applied voltage, 30 kV. Separation tube, 50 μm i.d. × 80.5 cm (effective length 72.0 cm). Detection, 206 nm. Temperature, 30 °C. (Reproduced from van der Griend and Groningsson,[108] with permission from Elsevier Science.)

sulfates, heparin, dextrans, dextrins, pentosan polysulfate, and dermatan sulfate, have been used as chiral selectors.[119–123] Dextran sulfate and pentosan polysulfate are semisynthetic sulfated polyanions. When charged polysaccharides are used as chiral selectors, the ionic character is important. In these polysaccharides, pentosan polysulfate has more ionizable groups per monomer unit (about two) than do chondroitin sulfates, dermatan sulfate (about one) and heparin, (one to two), and fewer than dextran sulfate (two to three). Enantiomers of tryptophan analogs[121] and basic pharmaceuticals[119–122] have been successfully separated by CE with ionic polysaccharides. One example is shown in Figure 13. Enantiomers of diltiazem hydrochloride (a Ca^{2+} channel blocker, in which the 2S,3S-form is active) and sulconazole (an antifungal, and a racemic drug) have been successfully separated by CZE using simply dextrin addition to a pH 2.5 phosphate buffer.[123]

Glycopeptide macrocyclic antibiotics such as vancomycin, teicoplanin, ristocetin A, and avoparcin, and some other antibiotics, such as rifamycins (B and SV), and aminoglycosides (kanamycin, fradiomycin, and streptomycin) appear to be among the most useful chiral selectors available for CE.[124,125] Recently, two different vancomycin analogs, namely A82846B and LY307599, and the teicoplanin family antibiotic MDL 63246 have been used to analyze negatively charged enantiomers.[124] High enantioselectivity has been shown by using these antibiotics, for example in HPLC with CSP moiety. However, some attention should be paid to the use of these

Figure 13 Enantiomer separations of diltiazem hydrochloride and sulconazole by CZE using 6% dextrin (JP grade) in 20 mM phosphate buffer, pH 2.5. Applied voltage, 30 kV. Separation tube, 75 µm i.d. × 47 cm (effective length 40 cm). Detection, 220 nm. Temperature, 20 °C. (Reproduced from Nishi et al.,[123] with permission from Vieweg Publishing.)

antibiotics in CE because their strong UV absorption affects the sensitivity of the technique.

Proteins such as bovine serum albumin, human serum albumin, α_1-acid glycoprotein, avidin, ovomucoid, casein, cellobiohydrolase, cellulase (fungal), transferrin (human serum), and pepsin, have also been found useful in CE for enantiomer separation.[126–128] Proteins have strong UV absorption in the typical UV detection wavelength range of 200–280 nm, therefore partial filling techniques have been used to avoid severe disturbances in UV detection.[127,128] This technique, where only a part of the capillary is filled with the selector, is also very useful in CE for enantiomer separations with antibiotics.

4.3.3 Micellar Electrokinetic Chromatography and Capillary Electrochromatography for Separation of Enantiomers

Chiral surfactants have been used for enantiomer separation in MEKC,[129,130] either when used on their own or in conjunction with other buffer additives such as CDs. Natural surfactants such as bile salts, digitonin, and saponins, and semi-synthetic surfactants derived from naturally occurring sugars[131,132] and amino acids[133,134] have been used. Recently polymerized surfactants have been used as chiral selectors in MEKC.[135,136] Compared with conventional micelles, which consist of a monomer surfactant, there are various advantages in polymer type micelles. The elimination of the dynamic equilibrium between the monomer and micelle may enhance chiral recognition. The critical micelle concentration of these polymer type micelles is essentially zero. This means that the polymer can be used over a wider range of concentrations. Organic modifiers can also be used without disrupting the formation of the micelle.

Separation by capillary electrochromatography (CEC) has recently attracted considerable interest due to the improved efficiency, as in conventional micro-HPLC. In addition, a wide variety of different packing materials developed for CEC are already available commercially.[137] The application of CEC has mainly focused on separations of electrically neutral drugs, because the separation mechanism of CEC is chromatography itself. Separation of enantiomers is another area where CEC holds tremendous potential. Capillaries packed with CDs as the immobilized stationary phases[138,139] have been used. A wide variety of CSPs such as polysaccharide derived,[140] naproxen derived, and Whelk-O,[141] have been prepared. MI has also been used in CEC to obtain capillaries with predetermined chiral selectivities.[142,143]

4.3.4 Regulatory Aspects

The acceptability of CE methods in drug analysis (including New Drug Applications (NDAs)) by regulatory authorities is one of the topics for pharmaceutical companies. Validations according to the ICH[144,145] or pharmacopoeia guidelines[146] are required in order that CE can be used as routine quality control methods by the pharmaceutical companies or when presenting NDAs. In modern, automated CE instruments, where a capillary is thermostated by an oven or liquid coolant, and sample injection and capillary washing are performed by computer, usually around 1% relative standard deviation (RSD) are obtained for the peak area ratios in the repeated injection (five or six injections). Accordingly, in the testing method of a drug, typically 2% or 3% values (corresponding to 2 RSD or 3 RSD values) are adopted as a criterion for the system suitability test (see below).

Appropriate CE data, meeting the requirements of ICH guidelines, have been included in a regulatory submission.[147,148] An assay that indicates the stability and uniformity of content of the cholesterol-lowering agent BMS-188494 by the MEKC method has been accepted as part of a regulatory submission to the

FDA.[147] A running buffer containing 0.1 M borate and 0.025 M SDS was used, and detection was carried out at 200 nm.

Pharmacopeia have also recognized the advancing application of CE within pharmaceutical companies. The savings in solvent purchase and disposal have been highlighted, particularly from an environmental viewpoint. Furthermore, a draft general chapter on CE has been published for the US Pharmacopeia (USP).[146] The first USP monographs describing CE were published in 1997.[149,150] These are chiral separation methods for epinephrine borate ophthalmic solution,[149] and a separate procedure for the analysis of ethambutol content in tablets.[150] In epinephrine borate injection, DM-β-CD has been used for separating the enantiomers (−)-epinephrine and (+)-epinephrine. Relative migration times, tailing factors of peaks, resolution and RSD values for replicate injections are specified in system suitability testing as follows. Both resolution values between the enantiomers, and the (−)-form and internal standards are not less than 1.5. Tailing factors for all peaks are not more than 2.5. An RSD of the ratio of (−)-epinephrine (active component) and (−)-pseudoepinephrine (internal standards) is not more than 3.0%. The relative migration times, resolution and RSD have been also specified in the assay of ethambutol. Resolution between the active component and internal standards is not less than 2. The RSD for the peak area ratio is not more than 2.0%. As a result of the ICH, groups representing the USP, European Pharmacopoeia and Japanese Pharmacopoeia have discussed the harmonization of general methods and monographs for drug substances. This has led to the publication of harmonized information concerning CE, as official inquiry stage draft.[151]

5 CONCLUSION

Recently, regulatory authorities have discussed the level of antipode and stereoselective analytical methods with industry associations. Some drafts such as ICH guidelines (Q3A, Q3B and Q6A) have been proposed. For chiral analysis and chiral purity determination in drug analysis, various CSPs have been developed and most are now available commercially. Further CE technology has also been used for chiral analysis because of its advantages. By using these technologies, a concentration of 0.1% of the minor enantiomer, can be easily determined, as required by regulatory authorities. In the near future, it is expected that more than 90% of enantiomers will be separated by using novel CSPs or chiral separation technologies. On the other hand, high sensitivity, nonseparated chiral purity determination methods using mass spectrometry (MS) or NMR technology may be introduced for drug analysis.

Many of the analytical techniques applied to the analysis of traditional pharmaceutical compounds are used to characterize combinatorial chemistry libraries. In both cases, the medicinal chemist is primarily concerned with verifying the identity and purity of the compounds synthesized. The identity of a compound usually is confirmed spectroscopically by Fourier transform infrared (FTIR) spectroscopy, mass spectrometry (MS), and/or nuclear magnetic resonance (NMR) spectroscopy, while purity is determined using a chromatographic technique, such as high-performance liquid chromatography (HPLC). Combinatorial chemistry libraries may contain 100–100 000 compounds present as single species or as mixtures. The need to efficiently characterize such large numbers of compounds has been the primary motivation behind the development of many of the chromatographic–spectroscopic techniques applied to the analysis of combinatorial chemistry libraries. Many of these techniques have utility outside of the realm of normal library characterization. For example, the combination of affinity chromatography and MS has proven useful for screening combinatorial chemistry libraries against specific biological targets. The major impediments to the analysis of combinatorial chemistry libraries have been the challenges of designing analytical methods compatible with the wide chemical diversity of compounds encountered in these libraries, and the unique sample preparation and handling requirements imposed by combinatorial synthesis.

1 INTRODUCTION

The drive to improve the efficiency of the drug discovery process has created the need for rapid compound synthesis and efficient methods for screening compounds for biological activity. The fields of combinatorial chemistry and high-throughput screening matured during the early 1990s to meet the challenges of modern pharmaceutical research. Solid-phase synthesis (SPS) and parallel solution-phase synthesis techniques have the potential to deliver hundreds of thousands of compounds in a relatively short period of time. However, the emergence of these combinatorial chemistry techniques has created the additional demand for new analytical techniques to follow the course of chemical reactions and characterize final products. This article begins with a brief overview of the basic concepts of combinatorial

chemistry, and follows with a description of many of the proven analytical techniques employed in combinatorial chemistry laboratories.

2 COMBINATORIAL CHEMISTRY

The field of combinatorial chemistry originally focused on the automated synthesis of peptide and small molecule libraries for drug discovery. Invariably, these compounds were assembled on chemical scaffolds immobilized on a solid support. However, with the rapid development of new technologies to synthesize compounds en masse, and the application of these techniques to fields outside of pharmaceutical research, the field of combinatorial chemistry has been in need of a more comprehensive definition. While a formal definition has yet to emerge, combinatorial chemistry may be described as a process of synthesizing sets of structurally related compounds by reacting all possible combinations of a limited number of chemical reagents according to a general reaction scheme in a manner compatible with the subsequent screening of the products for specific properties. The following sections provide an overview of the techniques that have emerged in the field of combinatorial chemistry.

2.1 Solid-phase Synthesis

The beginnings of modern SPS date back to Merrifield's work on solid-phase peptide synthesis (SPPS) in the early 1960s.[1] By the early 1970s a number of researchers, including Rapoport and Crowley,[2] Patchornik and Kraus,[3] and Leznoff and Wong,[4] had reported the preparation of nonpeptide heterocyclic compounds by solid-phase organic synthesis (SPOS). Automated peptide synthesizers became commercially available in the early 1980s. Further interest in SPS was sparked during this time by breakthroughs in phosphoramidite chemistry[5] which brought forth DNA SPS. A quantum leap in SPS during the mid-1980s grew out of the efforts of Geysen et al.,[6] Furka et al.,[7] Houghten,[8] Lam et al.,[9] and Fodor et al.[10] to increase the efficiency of SPPS through parallel synthesis. By the mid-1990s, many of the major pharmaceutical companies in the United States had established research groups to exploit the benefits of SPOS.

The primary advantages of SPOS over traditional synthesis are twofold. First, reactions on solid supports can be driven to completion through the use of excess reagents. Second, products can be isolated with reasonable purity by simply washing the excess reagents away with organic solvent. Using modern SPS techniques, it is possible to synthesize hundreds of thousands to millions of compounds simultaneously. Despite its universal acceptance in the pharmaceutical industry, SPOS is still in its infancy. The repertoire of synthetic organic reactions that have been carried out on solid-phase supports[11,12] represents only a small fraction of the chemistries available to the field of organic chemistry. A factor that has limited the use of SPOS in pharmaceutical research is the three to six month lead-time required to optimize new chemistries on solid supports.

The majority of SPS work is carried out on spherical polymeric supports (beads) composed of either polystyrene cross-linked 1–2% divinylbenzene, or polyethylene glycol–polystyrene block copolymer. A notable exception is the functionalized polyethylene–poly(*N*,*N*-dimethylacrylamide/methacrylic acid) graft copolymer ''pins'' developed by Geysen et al. for peptide epitope mapping.[6,13] The surface of the resin beads used in SPOS contains active functional groups (linkers), which serve as sites for attachment during synthesis. The structures of a number of the more common linkers used in SPOS are shown in Figure 1.

2.2 Mixture Synthesis

The most straightforward approach to synthesizing multiple compounds in parallel on a solid support is to treat an appropriate resin-bound intermediate with a solution containing equimolar quantities of various reagents. Cleavage of the reaction products from the solid support will yield, in theory, an equimolar mixture of the desired products. This is precisely the approach taken by researchers, such as Geysen et al.,[14] involved in the synthesis of peptide libraries in the mid-1980s. The potential of this technique, however, is less promising when one considers that the reactivity of a reagent is highly compound specific. Rather than providing an equimolar distribution of products, the method usually results in a wide distribution of product yields. When the technique is applied to peptide synthesis, small variations in the reactivity of amino acids can be overcome through variation of the concentration of each reagent in the reaction mixture.[15] If the reactions are very efficient, it is possible to obtain equimolar product mixtures by using only one equivalent of each reagent in the coupling step.[16] Mixture synthesis is generally impractical for the synthesis of nonpeptide libraries.

2.3 Split Synthesis

Furka et al.[17,18] developed the ''split synthesis'' strategy for parallel synthesis to overcome the difficulties involved in using reagents with different chemical reactivities. In the split synthesis technique, a common pool of resin-bound intermediates is divided into equal pools, each pool is coupled with a separate reagent, and the resin

Figure 1 Structures of common resin linkers used in SPOS.

pools are then recombined into one. Multiple iterations of dividing, coupling, and pooling resin beads result in a mixture of resin-bound products, where each single bead consists of only one set of product molecules. An example of the split synthesis of a library of nine hypothetical compounds is illustrated in Figure 2. The advantage of the split synthesis technique is that the number of products grows geometrically with each iteration of the divide–couple–pool cycle. For oligomers the number of possible products equals X^n, where X is the number of starting monomers and n is the number of reaction cycles.

2.4 Spatially Addressed Synthesis

Spatially addressed synthesis is a special case of parallel synthesis developed by Fodor et al.[10] at Affymax Research. The technique uses photolithography to synthesize arrays of up to 100 000 discrete compounds on silica wafers approximately 1 cm^2 in area. Active functional groups are attached to the surface of the silica substrate and their termini blocked with photolabile protecting groups (see Figure 3). Specially designed masks are laid over the surface of the silica wafer, and laser light is used to cleave exposed protecting groups from the surface. The wafer is then immersed in a reaction solution consisting of a reagent derivatized with a photolabile protecting group. The deprotected active sites on the silica wafer react with the protected reagents in the solution to form a protected oligomer. Peptide libraries may be synthesized through repeated application of the laser deprotection and coupling steps. The structure of any compound in the spatially addressable array may be inferred from its location on the silica surface and knowledge of the masking scheme and order of reagent additions.

2.5 Encoding Strategies

Combinatorial libraries prepared by split synthesis always result in mixtures, rather than discrete products. When a ''hit'' is obtained in a biological assay, it becomes necessary to identify the active member in the test mixture. Deconvolution of an active well usually involves iterative resynthesis and testing. An example of deconvolution of a 1000 component library of oligomers is shown in Figure 4. In this example, the combinatorial library is prepared by split synthesis involving ten sets

Figure 2 Split synthesis of a nine-member combinatorial library.

of monomers and three sequential reaction steps (i.e. $10 \times 10 \times 10 = 1000$) to give ten sets of oligomers. If the third well is biologically active, then the identity of the third monomer of the active compound is known from the last step of the synthesis. The identity of the second monomer of the active compound may be determined through resynthesis of a 100 component library by randomizing the first monomer, terminating the split at the end of the second reaction step, and fixing the position of the third monomer. In turn, the identity of the first

Figure 4 Deconvolution of a 1000-component library by iterative screening and resynthesis.

Figure 3 Light-directed, spatially addressable chemical synthesis. (Reprinted with permission from L.A. Thompson, J.A. Ellman, *Chem. Rev.*, **96**, 555–600 (1996). Copyright 1996 American Chemical Society.)

monomer of the active oligomer may be determined by fixing the positions of the second and third monomers.

The added burden of performing multiple resynthesis and the complications involved in deconvoluting libraries containing multiple active compounds have led researchers to devise other strategies for identifying the active components in mixture libraries. A number of encoding strategies have been developed by various researchers, and those based on DNA strands, peptide strands, molecular tags and radiofrequency (RF) transponders are described. Simply stated, an encoding strategy involves ''tagging'' resin beads at each step of a split synthesis, such that the identity of a compound on any bead can be determined by decoding the tag sequence. A generic example of library encoding is shown in Figure 5. The advantages of the encoding strategy are threefold. First, tagging schemes permit identification of all of the biologically active compounds in a mixture library, whereas deconvolution usually gives the most active library member. Second, rigorous analytical characterization of the library products is avoided, because compound identity is inferred from the tag sequence. A compound's identity can be verified faster by decoding a tag sequence, than by structural characterization. Third, encoding requires fewer synthetic steps than the iterative synthesis involved in library deconvolution. It is important to bear in mind, however, that the encoding process is independent of the reaction steps in split synthesis. Hence, failure of a reaction step will lead to an incorrect product assignment.

Figure 5 Encoding a solid-phase combinatorial library using molecular tags.

2.5.1 Oligonucleotide Tags

The first tagging strategy for combinatorial chemistry was reported by Brenner et al.[19,20] and involved encoding peptide libraries using oligonucleotide sequences. A pair of alternating combinatorial syntheses was used to attach the DNA strands and peptide monomers to separate sites on the bead surface. This encoding technique requires at least 15 nucleotides in the coding region for effective hybridization. Thus, a combinatorial synthesis involving five coupling steps would be encoded using combinations of triplets.

The library is decoded by amplifying the encoded oligonucleotide strands by the polymerase chain reaction (PCR), followed by DNA sequencing. The PCR amplification step provides enough sensitivity to allow single bead decoding. If multiple beads are decoded, separate PCR amplifications must be performed on each bead. A disadvantage of this encoding strategy is that the peptide products must remain immobilized on the bead surface during biological assay. Interference from the oligonucleotide tags could bias binding assays. Further, DNA strands are sensitive to temperature, redox reagents, and strong acids and bases, and hence they are of limited use in the synthesis of nonpeptide combinatorial libraries.

2.5.2 Peptide Tags

In a manner analogous to the use of oligonucleotide tags, peptides have been used to encode combinatorial libraries prepared by split synthesis. Two distinct applications of peptide encoding have been reported.[21,22] In the first approach, a bifunctional linker containing two orthogonal protecting groups is attached to a polystyrene resin. One of the protecting groups is acid labile and the other is removed by bases. The two sites on the linker serve as points of attachment for the peptide tag and the peptide ligand. A pair of alternating combinatorial syntheses is used to construct the ligand and tag on the solid support. The linker itself is acid labile, and is cleaved from the solid support prior to screening to yield a solution containing the coupled ligand/tag pairs. The active ligands are

isolated by affinity selection following biological assay. The identity of these active peptides is determined from Edman sequencing of the peptide tags.

Salmon et al.[22] devised a novel orthogonal release approach to screening and identifying active peptides in combinatorial libraries. Instead of relying on separate ligands and tags, the method uses a single peptide for both functions. Peptides are synthesized on an orthogonal linker possessing three pH sensitive cleavage sites, such that each linker molecule incorporates three copies of the peptide. In the assay procedure, approximately 500 resin beads are placed into each well of a 96-well microliter plate. A pH 4.5 buffer is applied to the beads to release the first third of the immobilized peptide molecules from the linker. The filtrate from each well is screened for biological activity, and the beads in the active wells are redistributed into clean assay plates as one bead per well. The single beads are treated with dilute base and the second peptide molecule from the linker is screened for activity. The identity of the active peptide is determined through Edman sequencing of the remaining peptide attached to the linker. Peptide sequencing by electrospray ionization mass spectrometry (ESIMS) and tandem mass spectrometry (MS/MS) also has been reported.[23]

2.5.3 Molecular Tags

To overcome the synthetic constraints imposed by the use of oligonucleotide and peptide tags, Still et al. developed a method for encoding combinatorial libraries using electrophoric tags.[24,25] Electrophoric tags are halogen-substituted phenoxyalkyl alcohols and are analyzed during library decoding by gas chromatography (GC) with electron capture detection (ECD). Prior to attachment on a polystyrene resin, the tag molecule is derivatized with an oxidatively labile linker (3-methoxy-4-hydroxybenzoic acid), and the linker's carboxylic acid group is converted to a diazoketone group. The derivatized tag is subsequently immobilized on the surface of the polystyrene resin through a metal-catalyzed carbene insertion reaction. The immobilized tags are extremely stable to the harsh conditions often encountered in organic synthesis, which has made this tagging technique ideally suited to the synthesis of nonpeptide combinatorial libraries.[26,27]

A novel feature of the encoding strategy developed by Still et al. is that the molecular tags are coupled through oxidatively labile linkers, while ligands are attached using photolabile groups. Molecular tags and ligands are released from the polystyrene support by independent mechanisms, thus eliminating interference during assay and decoding. In addition, the high sensitivity of ECD requires only picomoles of tag molecules for analysis. Hence, only about 1% of the loading capacity of the resin is required for tagging, leaving the bulk of the resin surface available for ligand immobilization.

As with other chemical tagging strategies, the preparation of combinatorial libraries encoded with molecular tags involves alternating cycles of ligand synthesis and encoding reactions. The choice of tag molecules and the sequence of their immobilization are based on their order of elution by GC. Molecular tags based on dialkylamines also have been reported.[28]

2.5.4 Radiofrequency Transponders

RF-encoded combinatorial chemistry makes use of miniature solid-state transponders to record encoding information during a split synthesis. These devices are encased in glass, which renders them inert to most organic reactions. Two types of RF transponder have been reported.[29,30] One type of transponder is designed to receive, store, and emit binary encoded RF signals. The specific reagents used in each step of a split synthesis are assigned unique bar codes by a computer, and these are transmitted to the transponder during synthesis. The entire synthetic pathway for a compound can be read from the information stored on the device. The second type of RF transponder does not store encoded data, but rather emits a unique numeric identifier when passed over a scanning device. A computer is used to track the reaction history for this second type of transponder in a split synthesis. The main advantages of RF transponders are that the encoding process does not require additional chemical reactions, and library decoding does not involve analytical characterization of molecular tags.

Figure 6 RF encoding of a single combinatorial library member. Multiple resin beads contained within the reactor are treated as a single unit during synthesis.

Both types of transponder are physically handled in the same manner. A set of porous capsules is filled with an appropriate resin, and a microchip transponder is placed inside each one (see Figure 6). The capsules are sealed and treated as individual reactors in a split synthesis. Organic reactions may be performed using conventional laboratory glassware,[31] and the capsules are easily manipulated manually, or with the aid of laboratory robots.

2.6 Solution-phase Synthesis

The application of liquid-handling robots to organic synthesis and the simultaneous design of apparatus for temperature control and agitation of multiple independent reaction vessels during the early to mid-1990s provided chemists with an attractive alternative to solid-phase combinatorial synthesis. Solution-phase synthesis is performed by reacting all possible combinations of a set of reagents in parallel. A primary advantage of solution-phase synthesis is that there is no need to develop strategies for the attachment of substituents to a solid support, or their subsequent cleavage.[11] Hence, lead times for reaction optimization are much shorter for solution-phase synthesis compared with SPS. Furthermore, solution-phase syntheses can be scaled to multi-milligram yields. Disadvantages of solution-phase synthesis are that the technique is limited to short reaction sequences, and the products can be difficult to purify. Most laboratories apply solution-phase synthesis to the generation of combinatorial libraries of discrete compounds, rather than mixtures. The population of solution-phase libraries is usually limited to only a few hundred compounds.

3 LIBRARY CHARACTERIZATION BY FOURIER TRANSFORM INFRARED SPECTROSCOPY

Infrared (IR) spectroscopy is a powerful sample characterization technique with broad application in organic and analytical chemistry. The mid-IR region provides both important functional group information ($4000-1300\,cm^{-1}$) and structural information ($1300-650\,cm^{-1}$). FTIR instruments are equipped with interferometers, which allow multiple spectral measurements of a sample to be made and averaged, and the resulting IR spectrum to be displayed in the frequency domain. The improvement in signal-to-noise that results from signal averaging affords FTIR instruments greater sensitivity than is possible with grating-based IR instruments. The high sensitivity of FTIR, its nondestructive nature, low cost, and ease of use make it ideally suited to reaction monitoring and final product characterization of combinatorial libraries.

While IR spectroscopy may be used quantitatively, its application to the characterization of organic molecules is usually qualitative. The widths of the bands in IR spectroscopy are quite narrow and lead to deviations from Beer's law over wide ranges of absorption. If quantitation is desired, the IR bands monitored should be reasonably wide and well resolved from nearby absorptions so that an accurate integration can be performed. The identity of a compound usually is confirmed by verifying the presence or absence of characteristic absorption bands in the product's IR spectrum. Changes in the intensity of specific bands in the IR spectra of reagents or product molecules are followed during reaction monitoring.

3.1 On-resin Analysis by Fourier Transform Infrared Spectroscopy

Rapid growth in the field of combinatorial chemistry during the mid-1990s lead to an increased interest in SPOS. The lengthy process of optimizing reaction strategies for use on solid supports has created the need for rapid and sensitive analytical techniques for monitoring solid-phase reactions. Ideally, a suitable technique for reaction monitoring would consume an insignificant amount of sample; involve little sample preparation; provide rapid analysis; possess high sensitivity; and have sufficient specificity to distinguish reagents from product. In traditional organic synthesis thin-layer chromatography (TLC) is the analytical technique of choice for monitoring reactions. FTIR spectroscopy has proven to be an equally capable technique for SPOS. Application of FTIR spectroscopy to reaction monitoring and final product characterization on solid supports is described in the following sections.

3.1.1 Fourier Transform Infrared of Pressed Potassium Bromide Pellets

Many of the early pioneers of SPS relied extensively upon IR spectroscopy to characterize resin-bound compounds. Crowley and Rapoport[32] quantitated the extent of chloromethylation of polystyrene resin based upon the H−C−Cl bending vibration at $1250\,cm^{-1}$ in the preparation of resin linkers for the Dieckmann cyclization of mixed esters. Frechet and Schuerch[33] characterized resin-bound intermediates by IR spectroscopy during a six-step synthesis of polystyrene linkers used in the SPS of oligosaccharides. Goldwasser and Leznoff[34] employed IR spectroscopy to characterize products from the SPS of monoester monoamides and monoester monoalcohols. Larsen et al.[35] followed the stepwise SPS

of a peptide using Fourier transform Raman spectroscopy (FTRS). Narita et al.[36,37] employed FTIR spectroscopy to characterize the conformation of peptides immobilized on polystyrene beads.

Preparation of samples for direct analysis by FTIR involves mixing approximately 10 mg of the resin beads with 190 mg of KBr, and compressing the mixture to form a pellet.[38] The quality of the resulting pellet is highly dependent on the pressing technique used, and the best results are obtained if the pressing die is warmed to 50 °C. The IR spectra of resin-bound products are usually obscured by absorptions from the polymer matrix, and background subtraction of the resin matrix is required to obtain interpretable sample spectra.

There are a number of disadvantages to treating resin-bound compounds like conventional solid samples during their preparation for analysis by FTIR. First, the KBr pellet technique consumes too much material. A 10-mg sample of 50-μm diameter resin contains approximately 100 000 beads, and most SPSs are carried out on less than 100 mg of resin. Second, this sample preparation technique is incompatible with mixture libraries prepared by split synthesis. The individual resin beads present in mixture libraries represent a number of unique products, and these must be characterized separately.

3.1.2 Single-bead Fourier Transform Infrared Microspectroscopy

Yan and Kumaravel[39] developed the technique of single-bead Fourier transform infrared microspectroscopy (SBFTIRM) to overcome the limitations of conventional FTIR analysis of bead-bound combinatorial libraries. The instrumentation required for SBFTIRM consists of a conventional FTIR instrument equipped with an IR microscope accessory. The IR microscope includes an $X-Y$ sample stage, a magnification objective, and a liquid-nitrogen-cooled mercury–cadmium–telluride (MCT) detector. Spectra may be obtained by conventional transmission mode, or by attenuated total reflectance (ATR). The latter technique detects only compounds on a resin bead's outer surface, whereas transmission mode IR spectra represent compounds on the surface and interior porous regions of the resin.

Sample preparation in SBFTIRM is straightforward. A drop of resin suspension is withdrawn from the reaction solution and the resin beads are washed with organic solvent and briefly dried under vacuum. The beads are placed on a NaCl window mounted on the $X-Y$ stage of the IR microscope. Spectra are recorded in transmission or ATR mode by averaging 64 scans from

Figure 7 SBFTIRM spectrum of (a) a single Merrifield bead and (b) a flattened bead. (Reprinted from B. Yan, G. Kumaravel, *Tetrahedron*, **52**(3), 843–848 (1996), with permission from Elsevier Science Ltd.)

a single resin bead. The FTIR spectra of compounds obtained in this manner are complicated by absorbances from the resin matrix. The quality of single-bead IR spectra can be dramatically improved by flattening the beads to a thickness of 10–15 μm between a pair of NaCl windows.[39] Comparison of the FTIR spectra obtained on a single Merrifield resin bead (Figure 7a) and a flattened bead (Figure 7b) illustrates the improvements in band shape and spectral resolution that result from the transmission of IR energy through a short, uniform pathlength.

SBFTIRM is superior to NMR and MS analyses in that the technique is extremely sensitive and does not require cleavage of the compound from the solid support. SBFTIRM is compatible with resin beads as small as

50 μm in diameter, and the technique has a detection limit of approximately 100 pmol of bound compound.[40] In addition, single-bead analysis by SBFTIRM produces spectra that are representative of the larger population of resin beads in SPS.

SBFTIRM has been used to measure the rates of a variety of organic reactions on solid-phase supports.[41–44] These experiments have helped dispel a number of myths surrounding SPOS.[45] Among the results are the following:

- the rates of organic reactions on solid supports are comparable to their counterparts measured in solution
- positioning the reactive site away from the bead surface through attachment of poly(ethylene glycol) spacers has no significant impact on the rates of organic reactions relative to rates measured on conventional resins
- comparison of the rates of solid-phase reactions monitored by transmission mode and ATR-mode SBFTIRM indicate that reaction kinetics on the bead surface and the bead interior are similar.

Overall, the technique of SBFTIRM is rapid, information rich, and has provided a greater understanding of SPOS.

3.1.3 Diffuse Reflectance Infrared Fourier Transform

Diffuse reflectance infrared Fourier transform (DRIFT) employing micro-sample-cups was developed by Deben et al.[46] as an alternative to conventional methods of FTIR analysis of resin-bound compounds. The micro-DRIFT technique requires only one tenth of the amount of resin used to prepare KBr pellets, and is simpler to perform than SBFTIRM. Sample preparation involves grinding 0.5–1.0 mg of resin with 30 mg of KBr, transferring the mixture into a DRIFT microcup, and placing the microcup into a nitrogen-purged DRIFT cell in the sample compartment of the FTIR. The micro-DRIFT technique yields FTIR spectra that compare favorably with spectra obtained by SBFTIRM. This technique, however, is not compatible with the characterization of mixture libraries prepared by split synthesis.

3.1.4 Photoacoustic Fourier Transform Infrared

Gosselin et al.[47] reported a simple, rapid, nondestructive technique to monitor solid-phase organic reactions based on photoacoustic Fourier transform infrared (PAFTIR) spectroscopy. PAFTIR spectroscopy measures the pressure variations of an inert gas above a sample that result from the sample's absorption of modulated IR radiation. This absorbed radiation heats the boundary layer of gas above the sample and sets up a pressure wave that is detected by a sensitive microphone. Multiple scans are averaged, and the resulting spectrum is Fourier transformed to the frequency domain. In contrast to transmission, ATR, and DRIFT techniques, PAFTIR is not susceptible to interference from light scattering and reflection by the sample. Approximately 10 mg of resin is required to obtain a reasonable spectrum, and no additional sample preparation is required. The resin may be used in subsequent reactions following PAFTIR. PAFTIR is not compatible with split synthesis SPOS.

3.1.5 Fourier Transform Infrared of Pins

Characterization of compounds attached to polyethylene pins by ATR/FTIR has been described by Gremlich and Berets.[48] In this technique, an internal reflectance probe is placed on a pin and pressed down to ensure good contact with the pin surface. Spectra are acquired in ATR mode and signal averaging is employed to improve the signal-to-noise ratio. The technique requires no sample preparation, is fast and nondestructive. Additional organic reactions may be performed on the pin surface following FTIR analysis.

3.1.6 Continuous Reaction Monitoring

Pivonka et al. developed a flow-through cell that allows solid-phase organic reactions to be monitored in situ by FTIR.[49] The flow cell consists of a 50-μm thick Teflon® gasket sandwiched between two IR transparent windows as shown in Figure 8. Inlet and outlet ports allow organic solvents to be pumped through the cell. The entire cell is mounted on the $X-Y$ stage of an IR microscope and spectra of individual resin beads may be recorded in transmission or ATR mode. The apparatus allows the FTIR analysis of multistep syntheses to be performed in real time.

Sample preparation involves placing a few resin beads near the center of the Teflon® gasket with the aid of a small drop of fluorolube gel. The flow cell is then assembled and positioned on the IR microscope. A series of solvents and reagents are passed through the flow cell, and FTIR spectra of the resin bead are collected at regular intervals during the synthesis. This approach to reaction monitoring has three advantages over SBFTIRM. First, continuous monitoring of reactions in situ does not require additional sample preparation. Second, this technique is compatible with monitoring organic reactions with short half-lives. Lastly, analysis of the same bead throughout an experiment makes it possible to enhance the FTIR spectra of resin-bound

Figure 8 Flow cell designed for in situ reaction monitoring of SPOS by FTIR. Side view of flow cell (a); exploded view of cell assembly (b). (Reproduced by permission of the Society for Applied Spectroscopy from D.E. Pivonka, K. Russell, T. Gero, *Appl. Spectrosc.*, **50**(12), 1471–1478 (1996).)

products through signal averaging followed by subtraction of the blank resin spectrum.

3.2 Off-resin Analysis by Fourier Transform Infrared Spectroscopy

Development of MS and NMR-based techniques for characterizing solution-phase combinatorial libraries has overshadowed analysis of these types of samples by FTIR. Indeed, widespread application of FTIR in combinatorial chemistry has been limited to the analysis of solid-phase libraries. Considerable research during the 1980s and early 1990s led to the development of suitable interfaces for coupling HPLC with FTIR spectroscopy. Many of the approaches to high-performance liquid chromatography/Fourier transform infrared (HPLC/FTIR) could be automated to perform flow-injection FTIR, or HPLC/FTIR analysis of solution-phase libraries. A description of several flow-through and solvent-elimination HPLC/FTIR interfaces available is given next.

3.2.1 Flow-through Fourier Transform Infrared Interfaces

A flow-through HPLC/FTIR interface provides a direct link between the liquid chromatograph and the IR spectrometer. Effluent from an HPLC column passes through a flow cell mounted within the sample compartment of an IR spectrometer. This arrangement allows IR spectra of eluting components to be recorded in real time. No sample preparation is required and solutes may be recovered after analysis. The major disadvantages of flow-through interfaces are that they suffer from low sensitivity, and are prone to losses of solute information due to regions of solvent opacity in the mid-IR.

3.2.2 High-performance Liquid Chromatography/ Fourier Transform Infrared Flow Cells

The first flow cells designed for HPLC/FTIR consisted of a spacer sandwiched between a pair of NaCl or KBr windows through which the column effluent passed.[50–52] These early designs, however, were of little practical value for routine compound analysis. Many of the solvents used in liquid chromatography (LC) absorb across regions of the mid-IR and interfere with solute detection. In addition, the use of strong IR-absorbing solvents severely limits the cell pathlengths that can be tolerated, which further reduces solute sensitivity. The use of IR-transparent solvents, such as $CHCl_3$ and $CDCl_3$, as eluants in normal-phase HPLC improves solute detection by FTIR,[53] but limits the types of solutes that may be characterized by the technique. Microbore (1 mm i.d.) HPLC columns operate at lower flow rates than analytical (4.6 mm i.d.) columns, thereby increasing solute concentrations in the mobile phase 20-fold. The use of microbore columns can help overcome the sensitivity limitations associated with the use of short pathlength flow cells in HPLC/FTIR.[54] A schematic diagram of a zero dead volume flow cell designed for microbore HPLC/FTIR is shown in Figure 9.[55] This flow cell has a pathlength of 0.45 mm, an internal volume of 0.33 μL, and can detect less than 50 ng of 2,6-di-*tert*-butylphenol at 3641 cm^{-1}.

Flow cells designed for reversed-phase HPLC/FTIR are based on ATR technology and constructed with ZnSe cell windows. In contrast to the HPLC/FTIR flow cells, IR radiation passing through an ATR cell penetrates only a few wavelengths into the exterior sample region per internal reflection. Thus, the effective pathlength of ATR flow cells is short enough to keep interference from water absorption to an acceptable level. McKittrick et al.[56]

Figure 9 Schematic diagram of a zero dead volume flow cell for microbore HPLC/FTIR. (Reproduced with permission from C.C. Johnson, L.T. Taylor, *Anal. Chem.*, **56**, 2642–2647 (1984). Copyright 1984 American Chemical Society.)

compared the performance of micro and ultramicro cylindrical internal reflectance (CIRCLE) cells for the detection of caffeine and theophylline by reversed-phase HPLC/FTIR. The micro CIRCLE cell had an internal volume of 24 μL and an effective pathlength of 4.65 μm, while the ultramicro CIRCLE cell had an internal volume of 1.75 μL and an effective pathlength of 3.18 μm. These types of flow cell, however, suffer from poor sensitivity. The detection limits for caffeine with the micro and ultramicro flow cells were 0.1 mg and 0.5 mg, respectively.

3.2.3 Solvent-elimination Interfaces for High-performance Liquid Chromatography/ Fourier Transform Infrared

Solvent-elimination interfaces for HPLC/FTIR overcome the disadvantages of solvent opacity and poor solute sensitivity characteristic of flow-through interfaces by removing the liquid solvent from solutes of interest prior to IR spectroscopy. These interfaces are compatible with many modes of chromatography, including normal-phase, reversed-phase, and gradient HPLC. The solvent elimination process concentrates solutes prior to analysis, and hence achieves high sensitivities with FTIR spectroscopy. The major disadvantages of solvent-elimination interfaces stem from their complexity and incompatibility with real-time analysis. Furthermore, volatile solutes may be lost during desolvation, and thermally labile compounds are susceptible to degradation. When used with aqueous solvents, these interfaces cannot tolerate flow rates greater than 0.5 mL min^{-1}. Three solvent-elimination interfaces for HPLC/FTIR are described below.

3.2.4 The High-performance Liquid Chromatography/ Diffuse Reflectance Infrared Fourier Transform Interface

The first high-performance liquid chromatography/diffuse reflectance infrared Fourier transform (HPLC/DRIFT) interface was developed by Kuehl and Griffiths[57] in the late 1970s. In this technique, the mobile phase exiting the column is deposited into a series of diffuse-reflectance cups filled with KBr. The chromatographic solvent is allowed to evaporate, and the DRIFT spectra of the solute residue on the KBr substrate are recorded. The HPLC/DRIFT technique provides greater solute sensitivity than flow-through interfaces,[58] but does not allow continuous analysis of the chromatographic eluant. Further, the quality of DRIFT spectra is dependent on the particle size of the KBr substrate, which can change during solvent evaporation. Conventional HPLC/DRIFT interfaces are not compatible with reversed-phase HPLC, because the KBr substrate is water soluble. However, Kalasinsky et al.[59] demonstrated that water could be eliminated from the mobile phase through post-column treatment with 2,2-dimethoxypropane. Water reacts with

2,2-dimethoxypropane stoichiometrically to yield two moles of methanol and one mole of acetone. Alternatives to chemical removal of water from reversed-phase eluants include: the use of industrial-grade diamond powder as a diffuse reflectance substrate;[60] solute extraction in methylene chloride prior to solute deposition on KBr;[61] and aqueous solvent removal with a heated nebulizer.[62]

3.2.5 Mono-disperse Aerosol Generation Interface for Combining High-performance Liquid Chromatography with Fourier Transform Infrared

The mono-disperse aerosol generation interface for combining high-performance liquid chromatography with Fourier transform infrared (MAGIC/HPLC/FTIR) was adapted from a similar device for coupling HPLC with MS.[63] A schematic of an HPLC system equipped with this interface is shown in Figure 10.[64] During operation, the HPLC mobile phase exiting the column is converted to a uniform stream of droplets in the aerosol generator. Dispersion of the droplets is achieved with the aid of a stream of helium gas. Solvent is removed by evaporation at ambient temperature, and solvent vapor and helium gas are removed from the stream of solute particles under vacuum. Solute particles are collected on the surface of an IR-transparent collection plate, which is moved continuously during analysis. IR spectra of the deposited solutes are collected off-line. MAGIC/HPLC/FTIR can remove solvents containing up to 100% water at flow rates of up to 1.0 mL min^{-1}.[65,66] The interface is compatible with the analysis of thermally labile compounds, and as little as 10–100 ng of deposited compound can be detected by FTIR.

3.2.6 The Reflectance–Absorbance Interface

Gagel and Biemann developed the continuously recording interface for HPLC/FTIR in the mid-1980s.[67,68] An illustration of the interface is shown in Figure 11. The effluent from an HPLC column is continuously sprayed onto the surface of a slowly rotating aluminum mirror. Solvent is evaporated by means of a stream of heated nitrogen. Solutes are deposited onto the surface of the aluminum mirror in a spiral pattern. The rotation speed of the reflective surface and the efficiency of solvent elimination govern the resolution between deposited solute bands. Reflectance–absorbance FTIR spectra of the deposited solute bands are collected off-line using a separate reading device mounted in the sample compartment of the IR spectrometer (see Figure 11c). Spectra obtained in this manner are susceptible to Christiansen scattering (i.e. a sudden rise on one side of an absorption band and a tailing on the other side) depending on the particle size of the deposited solute and refractive index changes that may occur in the vicinity of an absorption band. A representative FTIR spectrum of anthracene is shown in Figure 12.

A continuously recording interface for HPLC/FTIR is available commercially. The commercial instrument replaces the heated gas nebulizer in Gagel and Biemann's original design with an ultrasonic nebulizer and vacuum desolvation chamber, and solutes are collected on an aluminum-backed germanium disc instead

of an aluminum mirror. Detection limits are in the 10–100 ng range. This interface is compatible with both

Figure 12 IR spectra of anthracene: (a) transmission spectrum taken in a KBr pellet, and (b) that obtained using a continuously recording interface for HPLC/FTIR. normal- and reversed-phase HPLC, but only volatile buffers may be used in the mobile phase. Somsen et al.[69] incorporated a liquid–liquid extraction step upstream of solute deposition to make the interface compatible with the use of nonvolatile buffers (e.g. 10 mM potassium phosphate) in reversed-phase eluants.

4 LIBRARY CHARACTERIZATION BY MASS SPECTROMETRY

MS is one of the most sensitive analytical techniques available for the characterization of organic compounds. Modern mass spectrometers are capable of detecting low-molecular-weight organic compounds in the picomole to femtomole range. In addition to its high sensitivity, MS provides important molecular-weight and structural information that can be used to monitor reactions, or confirm the identity of final products. Specific compounds may be readily confirmed by noting the presence of characteristic molecular ions in a sample's mass spectrum. The inherent simplicity of MS data makes it possible to develop sophisticated algorithms to interpret

the mass spectra of combinatorial libraries in an efficient manner. Indeed, a number of commercial software packages are available for processing MS data and reporting sample results in condensed form. The development of similar tools for FTIR and NMR data reduction has languished due to the complexities involved in interpreting these types of spectra. Together these attributes have contributed to the widespread acceptance of MS among combinatorial chemists.

4.1 On-resin Analysis by Mass Spectrometry

MS can only detect ions in the gas phase. Compounds originating from SPS must be cleaved from the surface of the solid support prior to MS analysis, and the cleavage step can take up to 24 h to perform. From this perspective, MS is not as convenient a technique for reaction monitoring in SPS as SBFTIRM and magic-angle spinning (MAS) NMR spectroscopy. Nonetheless, the high sensitivities that can be achieved with MS make the technique ideally suited to the analysis of single resin beads. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOFMS) has emerged as the MS technique of choice for characterizing peptides and low-molecular-weight organic compounds covalently bound to solid-phase supports.

4.1.1 Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectrometry

Preparation of resin-bound samples for MALDI/TOFMS is tedious and difficult to fully automate. Before compounds obtained from SPS can be analyzed, they must be cleaved from the solid support and combined with a suitable ultraviolet (UV) absorbing matrix. The matrix is required for the matrix-assisted laser desorption/ionization (MALDI) process, and sample ionization efficiencies can be highly matrix dependent. Typical matrices employed in MALDI/TOFMS include 2,5-dihydroxybenzoic acid, α-cyano-4-hydroxycinnamic acid, and 3,5-dimethoxy-4-hydroxycinnamic acid. Procedures for cleaving a resin-bound compound depend on the nature of the linker employed in SPS. Compounds immobilized through acid-labile linkers can be removed by treating the resin with a solution of 1–2% trifluoroacetic acid (TFA) in dichloromethane. A more convenient method is to expose the resin beads to the acidic vapor produced from a solution of 15% TFA in dichloromethane for 3–5 min. Base-labile linkers can be cleaved using 1–2% ammonia in tetrahydrofuran (THF). Photo-labile linkers require treatment with UV light to cleave resin-bound compounds.

The application of MALDI/TOFMS to the characterization of peptide libraries has been reported by a number of research groups.[70–74] High-quality MALDI/TOFMS can be obtained from as little as 2–5% of the total peptide isolated from a single resin bead. In addition, MALDI/TOFMS may be used to assess the quality of a library by revealing the presence of deletion peptides, the products of side reactions and incomplete-deprotection products. Analysis of peptide libraries by imaging time-of-flight secondary ion mass spectrometry (TOF/SIMS) has also been reported.[75]

The characterization of nonpeptide bead-bound combinatorial libraries by MALDI/TOFMS requires the same sample preparation involved in the analysis of peptide libraries. Zambias et al.[76] characterized a peptoid attached via a Rink amide linker to a polymeric bead by MALDI/TOFMS employing 2,5-dihydroxybenzoic acid as a matrix. This same matrix was employed by Haskins et al.[77] to characterize the individual components of a five-member combinatorial library. Brummel et al.[78] reported that the MALDI/TOF mass spectrum of a angiotensin II antagonist (see Figure 13) synthesized on a polystyrene resin compared favorably with the electrospray ionization (ESI) mass spectrum of the same compound. Quantitative MALDI/TOFMS has been applied to study the incorporation of combinatorial libraries of porphyrins and peptide–DNA hybrids into liposome membranes.[79] An automated system for the analysis of combinatorial samples by matrix-assisted laser desorption/ionization Fourier transform mass spectrometry (MALDI/FTMS) was developed by Tutko et al.[80] The automated MALDI/FTMS instrument allows the characterization of 20 samples per hour and can be used for accurate mass determinations and MS/MS.

4.2 Off-resin Analysis by Mass Spectrometry

MS is typically applied to the characterization of libraries of compounds that have been cleaved from solid-phase resins, or that were synthesized in parallel by solution-phase techniques. Demands for high mass resolution, sensitivity, and speed of analysis place a number of constraints on instrument design. Automation requires that the samples be swept into the mass spectrometer in a liquid stream, as exemplified by flow injection analysis mass spectrometry (FIA/MS) and liquid chromatography/mass spectrometry (LC/MS) techniques. The design of interfaces that can both accommodate the introduction of analytes in solution and generate gas-phase ions suitable for mass analysis and detection is central to the successful application of MS in combinatorial chemistry.

4.2.1 Liquid Chromatography/Mass Spectrometry Interfaces

All LC/MS interfaces are designed to perform two basic tasks. First, they provide a mechanism for stripping solvent molecules from solutes present in the sample. These solute molecules are then converted into gas-phase ions prior to entering the mass analyzer. Depending on the design of the interface, the desolvation and ionization processes may occur under conditions of low vacuum or atmospheric pressure. The two most common sample introduction techniques used in the analysis of libraries of compounds present in solution are ESI and atmospheric pressure chemical ionization (APCI).

In the ESI process, the liquid sample is pumped through a narrow-bore capillary whose outlet is held at a potential of a few kilovolts relative to an opposing counter-electrode. A volatile electrolyte generally is introduced into the sample to increase the sample's ionic strength. The liquid becomes charged as it emerges from the electrospray capillary, and coulombic repulsion causes the stream to spread out as a plume of charged droplets. The mechanism leading to ion formation in electrospray is not well understood, but may be regarded as a process wherein charged droplets decrease in size through both evaporation and coulombic repulsive forces. Eventually these highly charged droplets reach a radius at which the electrical field gradient is large enough for ionized solute molecules to desorb from the droplet surface. The probable mechanisms involved in ESI have been described by Fenn[81,82] and Kebarle and Tang.[83]

A schematic diagram of a liquid chromatography/electrospray ionization (LC/ESI) interface is shown in Figure 14(a). ESI takes place at atmospheric pressure, and the sample ions formed are directed through a small orifice and a series of skimmers into the vacuum region of the mass spectrometer. An annular sheath gas surrounding the spray needle may be applied to enhance

Figure 14 Schematic diagram of (a) a LC/ESI interface for MS, and (b) an LC/APCI interface.

the desolvation process. The electrospray process is a soft ionization technique, yielding primarily $[M + H]^+$ or $[M - H]^-$ ions even with thermally labile and nonvolatile molecules. In addition, ESI can generate multiply charged ions, which makes the technique well suited to the analysis of biomolecules. Electrospray interfaces are generally operated at flow rates of 1–200 μL min^{-1}, with well-designed interfaces capable of flows as high as 1 mL min^{-1}. Liquid chromatography coupled with electrospray ionization mass spectrometry (LC/ESIMS) is generally performed using narrow-bore (2 mm i.d.) or microbore (1 mm i.d.) columns. If separations are carried out on analytical-scale (4.6 mm i.d.) columns, the column effluent usually is split to reduce the flow rate entering the electrospray interface. Coupling ESIMS with LC has been described in a number of review articles.[84,85]

In APCI, a heated nebulizer is used to remove solvent from the solute prior to the ionization step. As its name implies, sample ionization in APCI takes place at atmospheric pressure. A schematic diagram of a representative atmospheric pressure chemical ionization mass spectrometry (APCIMS) interface is shown in Figure 14(b). The liquid sample enters the APCI interface through a narrow capillary around which a concentric flow of nitrogen gas is provided to pneumatically generate a fine aerosol. An additional flow of nitrogen makeup gas helps direct the sample aerosol towards the heated region of the APCI probe. The temperature of the probe is maintained such that effective desolvation and solute volatalization are achieved. The vaporized aerosol then passes by a corona discharge needle held at a potential of 2 kV, where chemical ionization of the solute is achieved in the surrounding solvent vapor at atmospheric pressure. The solvent vapor serves as a reagent gas for the formation of the reactant ions necessary in the chemical ionization process. The solute ions produced through ion–molecule reactions with the reagent gas then enter the intermediate pressure region of the mass spectrometer through a sampling cone. The sampling cone is maintained at 10–100 V to help dissociate analyte–solvent cluster ions before the analyte ions pass through a skimmer on their way to the mass analyzer.

The transport regions used in APCI and ESI interfaces are nearly identical in design, and most modern systems allow rapid conversion between the two interface types.[86] APCI interfaces are compatible with liquid flow rates as high as 1–2 mL min^{-1}. As with ESI, APCI generally produces little fragmentation, although sample fragmentation can be induced where desired by increasing the voltage of the sampling cone. The two ionization techniques differ in the greater abundance of multiply charged ions that are observed in ESI mass spectra.

4.2.2 Electrospray Ionization Mass Spectrometry

ESIMS is well suited to the analysis of low-molecular-weight (e.g. 10–1000 Da) organic compounds containing ionizable functional groups and large molecules (e.g. $>10^3$ Da) with moderate to high polarity. It is not surprising, therefore, that ESIMS is the ionization technique most often applied to the MS characterization of combinatorial libraries. Analysis of nonpeptide libraries by ESIMS has focused mainly on the characterization of single compounds cleaved from individual resin beads,[87–89] or single compounds obtained from parallel synthesis.[90,91] The ESIMS spectra of low-molecular-weight organic compounds generally are characterized by singly charged molecular ions, and multiply charged ions are only rarely observed. Compounds containing basic functional groups yield intense positively charged molecular ions with little fragmentation. Hydrophobic molecules are more difficult to ionize by addition of a proton in ESIMS, and hence have a higher tendency to fragment.

Dunayevskiy et al.[92] employed ESIMS to study the composition of six sub-libraries synthesized to mimic the diversity present in a 65 341 component mixture library. Analysis of the 36–55 member sub-libraries provided qualitative information on the yields of synthetic reactions used to generate the mixture library, and hence insight into the library's actual composition. This work illustrated a number of difficulties that may be encountered when

characterizing mixtures of small organic molecules by ESIMS. First, peak intensities do not directly correlate with sample concentration due to differences in ionization efficiency among organic compounds present in mixtures. Furthermore, polar solvents such as dimethyl sulfoxide (DMSO), used to prepare combinatorial libraries for biological testing, have a tendency to form intense adduct ions with library compounds. Complete suppression of product molecular ions in a combinatorial library by DMSO adduct ions has been reported by Kyranos and Hogan.[93] Separation of the solute from the solvent by reversed-phase chromatography prior to MS analysis is an effective means of eliminating DMSO adduct formation.

The likelihood of a small-molecule mixture library containing isobaric compounds increases as the population of the library grows, hence direct application of ESIMS with nominal mass resolution to large mixture libraries is not practical. The instrumentation and data precision requirements for the MS determination of structures from combinatorial mixtures have been described by Blom.[94] In addition, Hughes[95] devised a rules-based strategy for designing combinatorial syntheses such that libraries of low-molecular-weight organic molecules always contain unique nominal product masses.

ESIMS is an extremely useful technique for the characterization of peptide libraries containing mixtures. Metzger et al.[96,97] were the first to apply ion-spray and ESIMS to the analysis of synthetic peptide libraries. Side-reactions during SPPS can lead to peptide libraries that deviate significantly from expected molar composition. MS is ideally suited to peptide analysis, because it can readily distinguish between peptides differing by as little as one amino acid. While a number of MS ionization techniques are available for peptide analysis, many suffer from ion suppression effects. Ionization of some components present in a mixture may be partially or completely suppressed, even though the same compounds yield intense ions when analyzed separately. Ionization yields for individual peptides present in mixtures with ESIMS, however, have been reported to be nearly identical.[98] Lambert et al.[99] reported that a single peptide possessing a unique mass may be identified from a library containing up to 100 000 peptides using a combination of LC/ESIMS with selected ion monitoring. The feasibility of characterizing peptide mixtures by MS has been explored mathematically using computer simulations of mass spectra for peptides containing 2–7 amino acids.[100] ESIMS also has been used to automate the purity assessment of synthetic peptides.[101] The total ionizable material present in a sample is compared with the intensity of the target peptide and each of the identifiable contaminants present in order to arrive at an estimation of sample purity.

4.2.3 Atmospheric Pressure Chemical Ionization Mass Spectrometry

Moderately polar compounds within a mass range of 100–1000 Da ionize readily by APCI. APCI generally produces greater fragmentation and fewer multiply charged ions than ESI does. While fragment ions in a mass spectrum can complicate spectrum interpretation, their presence often helps confirm structure identity. These characteristics make APCI well suited to the identification of nonpeptide organic compounds. The ionization process in APCI can produce both positively and negatively charged molecular ions, and predicting the relative intensities of the two for a given compound can be difficult. Iwabuchi et al.[102] examined the intensities of the molecular ions observed in positive-ion and negative-ion mode APCI for a series of hydroxymethylglutaryl–Coenzyme A reductase inhibitors. Lipophilic compounds in the series gave more intense molecular ions in positive-ion mode, while hydrophilic compounds gave more intense negatively charged molecular ions. Further, it is not often easy to predict whether APCI or ESI will be better suited to a given combinatorial library. Hence the designs for automated systems for high-throughput library characterization often make provision for both types of ionization technique in conjunction with positive and negative ion detection.[103] Positive-ion mode APCIMS has been applied to the characterization of a variety of organic compound classes, including quinolones,[104] pyrazoles,[105] and dihydropyridones.[106]

4.2.4 Tandem Mass Spectrometry

MS/MS is based on a simple fragmentation experiment in which a parent molecular ion dissociates into a corresponding product ion and neutral fragment molecule. The parent molecular ion may be positively or negatively charged, and the product ions produced have the same charge as the parent ion. MS/MS historically has been performed using triple quadrupole instruments, wherein the first and third quadrupoles are used to scan parent and product ion masses, and the intermediate quadrupole is employed as a collision chamber. Fragmentation of parent ions emitted from the first quadrupole is achieved through a process known as collision-induced dissociation (CID). Argon, nitrogen, methane, or ammonia gas are introduced individually or as mixtures into the second quadrupole. Collisions between parent ions and target gas molecules increase the internal energy of the parent ions. This collisional activation is followed by fragmentation into product ions and neutral fragment molecules. MS/MS may also be performed on ion-trap mass spectrometers.[107] When carried out on ion-trap instruments, these experiments involve tandem

operations over time in the same space, whereas MS/MS experiments on triple quadrupole instruments involve tandem operations in different regions of space.

There are three basic types of MS/MS experiments: the product-ion scan, the neutral-loss scan, and selected reaction monitoring. A description of each of these experiments carried out on a triple-quadrupole instrument is given below. The product-ion scan provides a fragmentation mass spectrum of a single parent ion. The m/z of the parent ion is fixed by the first quadrupole, and the masses of all of the product ions formed from CID of the parent in the second quadrupole are scanned by the third quadrupole. A product-ion scan can be used to distinguish between multiple components introduced directly into the mass spectrometer as a mixture, or as a single band eluted during a chromatographic separation. A neutral-loss scan involves setting the first and third quadrupoles such that they scan for a constant difference in mass between the parent and product ions. The first quadrupole passes a select range of incoming parent ions into the collision region defined by the second quadrupole. Of the product ions generated through CID, only those with a specific mass difference from their respective parent ions are scanned by the third quadrupole. The mass difference between scans of the first and third quadrupoles equals the mass of the neutral fragment from CID of the parent ions. The neutral-loss experiment is used to confirm the presence of specific functional groups that are known to yield characteristic neutral loss molecules, such as CO_2 from carboxylic acids, or NO radicals from nitroaromatic compounds. A selected reaction monitoring experiment is performed by fixing the first quadrupole to pass a single parent ion to the collision chamber, and setting the third quadrupole to pass only one product ion fragment. While selected reaction monitoring provides less structural information than the other two MS/MS experiments, the technique delivers greatly enhanced sensitivity. The sensitivity enhancement results from a decrease in instrument noise, and the selected reaction monitoring experiment is best suited to the analysis of trace amounts of compound, such as single-bead characterization.

While MS/MS experiments can be performed on ion-trap instruments, the processes involved differ from those executed on triple-quadrupole mass spectrometers. For example, a product-ion scan carried out on an ion-trap mass spectrometer involves scanning the RF voltage to eject all ions in the trap, up to but not including the ion of interest. These trapped ions then undergo collision with a background gas inside the ion-trap chamber. The product-ion spectrum is recorded by ramping the RF voltage a second time to eject product ions from the trap. A distinct advantage of ion-trap instruments is that a product ion from the initial CID can be trapped and subjected to an additional CID cycle, and this process may be repeated through many generations of product ion. The ability to perform such MS^n experiments on ion-trap mass spectrometers provides the combinatorial chemist with a powerful tool for structure elucidation.

MS/MS has a number of possible applications to combinatorial chemistry, including structure characterization, identification of side products, deconvolution of isobaric mixtures, single-bead analysis, and library decoding. Keough et al.[108] employed a hybrid magnetic sector/orthogonal acceleration single-pass time-of-flight (TOF) mass spectrometer to measure the exact masses of product ions formed during MS/MS studies of compounds

Figure 15 Product-ion mass spectrum of two isomeric 8-mer sequences, UGACACTG ●, w series ions; ○, a-base series ions and TGACACUG (■, w series ions; , α-base series ions). from combinatorial libraries. In this work, the combination of exact mass measurement with MS/MS proved crucial to characterizing a major side-product present in a combinatorial sample, and differentiating between isobaric residues in peptides. Pomerantz et al.[109] developed a MS/MS procedure that allows sequence analysis of mixtures of closely related oligonucleotides. Oligonucleotide sequencing involves performing a product-ion scan on each of the parent ions observed in the sample mixture. Mixtures containing oligonucleotides with the same mass yield product-ion mass spectra with partially overlapping signals. Proper interpretation of these spectra requires application of special algorithms, which are based on fragment-ion abundance patterns observed in sequencing of single oligonucleotides. The product-ion spectrum of two isomeric oligonucleotides is shown in Figure 15.[109] MS/MS has also been used to decode secondary amine tags cleaved from resin beads following SPOS.[110] In this example, a separation step was required to resolve isobaric masses prior to MS/MS in parent-ion scanning mode. Dansylated secondary amine tags could be detected unambiguously at the femtomole level, making the technique compatible with decoding of single resin beads.

5 LIBRARY CHARACTERIZATION BY NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

NMR spectroscopy is an information-rich technique for probing the structure of organic compounds. NMR spectroscopy can be used to differentiate between most structural, conformational, and optical isomers. The chemical shift information and coupling constant parameters provided by ^{1}H NMR allow specific protons within an organic molecule to be assigned unambiguously. By performing heteronuclear ^{1}H/^{13}C shift and homonuclear shift correlated experiments, the exact structure of an organic molecule may be determined. In contrast to MS, NMR spectroscopy is a noninvasive and nondestructive technique. A sample may be recovered after a NMR experiment and used in subsequent analyses.

5.1 On-resin Analysis by Nuclear Magnetic Resonance Spectroscopy

Because it is a powerful tool for structural characterization of small organic molecules, there has been significant interest in the application of NMR spectroscopy to combinatorial chemistry. However, conventional NMR techniques are only compatible with homogeneous samples. Hence, characterization of compounds originating from SPS by standard NMR requires that the products be cleaved from the solid support prior to analysis. This presents a significant barrier to the characterization of resin-bound intermediates and reaction monitoring by NMR. Two sample-handling techniques that are amenable to the NMR analysis of resin-bound compounds are standard NMR using gel-phase samples, and MAS NMR. These gained wide acceptance within the combinatorial chemistry community during the 1990s and are discussed below.

NMR spectroscopy is most effective when the spectra of organic compounds possess good spectral resolution (i.e. narrow linewidths). There are two major factors that work to broaden the linewidths observed in NMR. The first of these is magnetic susceptibility inhomogeneity. All compounds possess an inherent magnetic susceptibility, which is a measure of how the compound affects a surrounding magnetic field. In an NMR experiment, a homogeneous sample will produce a uniform change in the applied magnetic field, and this can be corrected by a process called ''shimming''. A resin-bound compound, however, is heterogeneous, and possesses regions of differing magnetic susceptibility that cannot be corrected by shimming. These magnetic susceptibility mismatches result in broadening of the normal NMR linewidths. Second, significant rotational freedom is required to overcome the dipolar splittings and chemical shift anisotropy present in rigid molecules.

The quality of NMR spectra obtained with solid-phase resins depends primarily on the resin structure, with choice of solvent playing a secondary role.[111,112] Many of the resins used in SPS are based on cross-linked polystyrene that is functionalized with linker molecules attached to the polymer surface through tethers of varying length. The length of the tether influences the mobility of compounds attached to the resin. Tentagel™ resins have the longest tethers, and hence provide the narrowest observed NMR line widths. Wang type resins have short tethers and restrict the mobility of attached compounds. Compounds attached directly to polystyrene with no tether produce NMR spectra of poor quality. The shorter the tether on the polymer support, the more important proper choice of solvent becomes to produce quality NMR spectra. Resins swell to different degrees in various solvents, and the greater the extent of swelling the narrower the NMR line widths will be. Chloroform-*d*, dichloromethane-d_2, benzene-d_6, dimethylformamide-d_7, and THF-d_8 all provide significant swelling of polystyrene-based resins. Dichloromethane-d_2 is generally preferred as a solvent because it provides the highest degree of swelling and its high volatility facilitates recovery of the resin after analysis. Methanol-d_4, D_2O, acetonitrile-d_3, and dimethylsulfoxide-d_6 do not appreciably swell polystyrene-based resins and are poor solvent choices for monitoring SPS by NMR.

5.1.1 Gel-phase Nuclear Magnetic Resonance

While ^{1}H NMR is sufficiently sensitive to permit rapid analysis of solid-phase reactions, the signals obtained from resin samples by the gel-phase approach are typically too broad to be useful for structural determinations. Standard NMR of gel-phase samples is generally limited to the detection of heteronuclei such as ^{13}C, ^{19}F, ^{15}N, and ^{31}P, where there is significantly greater chemical shift dispersion than in ^{1}H NMR. The linewidths observed in ^{1}H NMR of gel-phase samples are typically greater than 100–300 Hz.

Gel-phase NMR spectra are obtained using conventional NMR sample tubes and high-resolution NMR spectrometers. Sample preparation involves placing between 50 and 100 mg of resin in a 5-mm NMR tube and adding sufficient deuterated solvent (0.2–0.3 mL) to cover the solid sample. Sonication or vortexing of the tube's contents may be necessary to achieve a uniform gel. Solvent molecules entrained in a different environment within the solvent-swollen polymer matrix can lead to a second set of resonances in the NMR spectra of the gel samples. This can be corrected by using a significant excess of solvent, or by preswelling the resin with the solvent prior to placing it into the NMR tube.

Gel-phase ^{13}C-NMR was employed extensively during the 1970s and early 1980s as an analytical technique to follow SPPS. Sternlicht et al.[113] pioneered gel-phase ^{13}C-NMR to characterize amino acids bound to cationic exchange resins. Leibfritz et al.[114] employed gel-phase ^{13}C-NMR in conformational studies on polypeptides bound to poly(oxyethylene) supports. The first application of gel-phase NMR to follow resin-bound intermediates in SPS was reported by Epton et al. in 1980.[115] In this work, the step-wise synthesis of polypeptides on a phenolic cross-linked poly(acryloylmorpholine)-based matrix was monitored by recording the ^{13}C-NMR spectra of the resin following purification by recrystallization. The choice of the resin matrix was based on its superior swelling characteristics over poly(styrene) matrices in polar organic solvents, such as DMSO, that solubilize peptides well. Giralt et al.[116] followed the step-wise synthesis of the peptide H–Asn–(N–Me)–Ala–Thr–NH_2 on a benzhydrylamine resin by gel-phase ^{13}C-NMR. Both Epton et al. and Giralt et al. reported that narrow signals are obtained for carbons that are further away from the polymer backbone, while the NMR signals for carbons close to the backbone broaden and diminish in intensity as the peptide chain grows. The latter is attributed to decreased mobility of nuclei nearer the support.

Application of gel-phase NMR in SPOS was first reported by Manatt et al.[117] in 1980. In 1982, Jones et al.[118] employed gel-phase ^{13}C-NMR to characterize resin-bound intermediates from the SPOS of insect pheromones. As with gel phase ^{13}C-NMR of peptides, the

Figure 16 Fast ^{13}C-NMR monitoring of a stepwise reductive amination sequence. (Reproduced with permission from G.C. Look, C.P. Holmes, J.P. Chin, M.A. Gallop, *J. Org. Chem.*, **59**, 7588–7590 (1994). Copyright 1994 American Chemical Society.)

resonances of carbon atoms close to the polymer backbone were observed to be broadened relative to those associated with side chains of the resin-bound intermediates. Blossey et al.[119] reported the gel-phase ^{13}C-NMR characterization of resin-bound steroids obtained by SPOS on dehydrocholic and cholic acids immobilized on chloromethylated poly(styrene–2% divinylbenzene). Correlation with solution-phase ^{13}C-NMR spectra permitted complete assignment of each of the resonances observed in the gel-phase ^{13}C-NMR spectra of the resin-bound steroids.

Gel-phase ^{13}C-NMR involves averaging thousands of transients to improve signal-to-noise, making the technique impractical for monitoring reactions in real time. The long analysis times required in ^{13}C-NMR are primarily due to the low natural abundance of the ^{13}C isotope. By using ^{13}C enriched reagents, Look et al.[120,121] have reported obtaining high-quality NMR spectra from as few as 64 transients. Fast ^{13}C-NMR analysis requires as little as 20 mg of resin, and can be performed within 15–30 min with most of this spent drying the resin sample. Representative ^{13}C-NMR spectra from a stepwise reductive amination sequence are shown in Figure 16. The limited availability of ^{13}C-enriched intermediates may make this characterization technique impractical for some SPOS applications.

Manatt et al.[122] incorporated ^{19}F nuclei into amino-protecting groups and used these to monitor SPPS by gel-phase ^{19}F-NMR. These intermediates were immobilized on 1% cross-linked, chloromethylated polystyrene, and provided reasonably narrow NMR linewidths. Loadings as low as 0.005 mequiv g^{-1} could be detected by gel-phase ^{19}F-NMR.

Swayze[123] incorporated isotopically enriched [^{15}N]alanine in the synthesis of a combinatorial library of 3,4,8-trisubstituted 1,4-diazabicyclo[3,4,0]nonan-2-one compounds. The labeled amino acid nitrogen was involved in the formation of the key heterocyclic ring via an intramolecular Mitsunobu reaction, the formation of which was monitored by gel-phase ^{15}N-NMR.

Gel-phase ^{31}P-NMR has two advantages over ^{13}C-NMR for characterizing phosphorus-containing compounds immobilized on solid supports. First, the 100% natural abundance of the ^{31}P isotope makes the technique 383 times more sensitive than ^{13}C-NMR. Spectra can be obtained in as little as 10 min using the same sample preparation techniques described for gel-phase ^{13}C-NMR. Second, most polymer resins used in SPS do not contain phosphorus, and hence do not interfere with the observed resonances in ^{31}P-NMR. Bardella et al.[124] were the first to apply ^{31}P-NMR to the characterization of oligonucleotides prepared by SPS. The technique has also been applied to monitor the SPPS of phosphotyrosine-containing peptides.[125] Johnson and Zhang[126] used gel-phase ^{31}P-NMR to monitor the Horner–Wadsworth–Emmons synthesis of a combinatorial library of alkenes. Completion of this reaction is indicated by the disappearance of the multiplet at δ 22 due to the resin-bound diethylphosphonoacetamide starting material and the simultaneous appearance of a broad resonance for diethylphosphonate at δ 0. Quarrell et al.[127] studied the ^{31}P-NMR spectra of α-triphenylphosphonium-*p*-toluic acid bromide in solution and immobilized on Tentagel™ resin in order to characterize the mobility of compounds immobilized on this widely used solid-phase support.

5.1.2 Magic-angle Spinning Nuclear Magnetic Resonance

In solution, rapid isotropic motion averages the dipolar splittings and chemical shift anisotropy to zero, which yields sharp lines in the corresponding NMR spectrum. In solids, both the dipolar coupling and the chemical shift anisotropy contain an angular dependence of the form $(3\cos^2\theta - 1)$. This angular dependence becomes zero when θ equals roughly 54.73°, hence this angle is referred to as the ''magic angle''.

Characterization of cross-linked polystyrene gels by ^{1}H-MAS NMR was first reported in the mid-1980s.[128] A lack of suitable techniques for determining the structure of resin-bound compounds led to the investigation of ^{1}H MAS NMR as an analytical tool for SPOS beginning in the mid-1990s. The acquisition of high-resolution ^{1}H-MAS NMR spectra, however, would not have been possible were it not for the development of NMR probes that combined the use of both MAS and ''magnetic-susceptibility-matched'' materials. Indeed, the first reported 500 MHz ^{1}H-NMR spectrum of a resin-bound compound was recorded using the Nano-NMR™ probe commercialized by Varian Instruments (Palo Alto, California).[129] A comparable high-resolution MAS probe is available from Bruker (Rheinstetten, Germany). A comparison of a 16-scan 500 MHz ^{1}H-NMR spectrum of a resin-bound compound obtained using a conventional 5-mm liquids probe with that obtained by ^{1}H-MAS NMR using a Nano-NMR™ probe is shown in Figure 17. In addition to providing a significant improvement in resolution through removal of magnetic susceptibility line broadening, the MAS probe required only one tenth of the sample used in the conventional liquids probe.

Modern MAS probes designed for combinatorial analysis are sensitive enough to allow ^{1}H-MAS NMR spectra to be obtained on single resin beads. The ^{1}H-MAS NMR spectra from the stepwise SPS of a hydantoin precursor are shown in Figure 18.[130] Sample preparation involved swelling a single macro bead in DMSO-d_6 and placing it in a Bruker MAS probe. The spectra were generated within 6–8 min by averaging 128–168 scans. The observed

Figure 17 A 500 MHz ^{1}H-NMR spectrum of a resin-bound compound (a) obtained with a conventional 5-mm liquids probe (b) and a 500 MHz ^{1}H-MAS NMR spectrum of the same compound using a Varian Nano-NMR™ probe (c). (Reproduced with permission from W.L. Fitch, G. Detre, C.P. Holmes, J.N. Shoolery, P.A. Keifer, *J. Org. Chem.*, **59**, 7955–7956 (1994). Copyright 1994 American Chemical Society.)

line widths were in the order of 5–8 Hz. Sarkar et al.[131] have reported similar success in obtaining ^{1}H-MAS NMR spectra from single resin beads using the Varian Nano-NMR™ probe. Chin et al. applied MAS NMR to reaction monitoring and structure determination of compounds attached to multipin crowns.[132]

The quality of the spectra obtained by ^{1}H-MAS NMR can be enhanced by applying a small decoupling pulse to the signal prior to data collection (presaturation). In some cases, ^{1}H-MAS NMR spectra are complicated by the presence of broad peaks related to the polystyrene matrix of the resin. Garigipati et al.[133] have reported that this type of interference from the resin matrix can be eliminated by application of spin-echo pulse sequences in the ^{1}H-MAS NMR experiments.

Stöver and Fréchet[134] demonstrated the superiority of ^{13}C-MAS NMR over gel-phase ^{13}C-NMR in the characterization of solvent-swollen polymers. The narrow line widths observed in the MAS spectra were attributed to the cancellation of residual motional anisotropy within the polymer network. The first application of ^{13}C-MAS NMR to combinatorial chemistry involved the structural characterization of norborane-2-carboxylic acid epimers attached to a polystyrene resin.[135] The ^{13}C-MAS NMR spectrum of the resin yielded sharp signals for all of the carbons in the norbornyl system, with an average resolution of 13 Hz. Remarkably, the ratio of peak intensities in the ^{13}C-MAS NMR spectrum suggested a 60 : 40 *exo/endo* ratio of epimers on the resin, whereas the ratio of epimers in nonbound norborane-2-carboxylic acid is 70 : 30.

Macdonald et al.[136] applied ^{31}P MAS NMR to the characterization of oligonucleotides covalently bound to controlled porous glass beads. Changes in the oxidation state of the phosphorus atom and the addition or removal of protecting groups were readily apparent from the shifts in the resonances observed in the ^{31}P MAS NMR spectra. However, the spectra of many of the oligonucleotides consisted of isotropic ^{31}P resonances. Thus, ^{31}P MAS NMR cannot distinguish between di- and trinucleotides, or between linear and branched trinucleotides immobilized on controlled porous glass beads.

The high quality of MAS NMR spectra allows the same types of two-dimensional (2-D) NMR experiments that are performed to assess the structure of compounds in solution to be carried out on solid-phase supports. The first total structural assignment of a resin-bound compound by NMR was reported in 1995.[137] Heteronuclear multiple quantum coherence (HMQC) spectroscopy and total correlation spectroscopy (TOCSY) MAS NMR spectra for Wang-bound Fmoc-lysine-*t*-butoxycarbonyl (Boc) (see Figure 19) enabled complete assignment of the aliphatic resonances in the compound.

While the line widths in ^{1}H-MAS NMR spectra are sufficiently narrow to distinguish between protons based on chemical shift information, they are too broad to reveal couplings. Shapiro et al.[138] have reported that coupling information can be obtained from resin-bound compounds by performing 2-D *J*-resolved NMR experiments. Spin-echo correlated spectroscopy (SECSY) can

simultaneously provide spin connectivity and coupling information[139] for protons in resin-bound molecules. SECSY data contains the same connectivity information provided by homonuclear shift correlation spectroscopy (COSY), but retains the enhanced resolution of 2-D *J*-resolved experiments.

Nuclear Overhauser effect (NOE) spectroscopy is routinely applied to characterize the three-dimensional (3-D) structure of peptides and proteins in solution. Several research groups have used NOE analysis to determine the secondary structure of resin-bound peptides.[140,141]

5.2 Off-resin Analysis by Nuclear Magnetic Resonance Spectroscopy

Despite the strengths of NMR as a powerful spectroscopic method, it is difficult when using most NMR techniques to distinguish between a compound of interest and any impurities or contaminants that may be present in the sample. Structure elucidation of mixtures of unknown organic compounds with overlapping ^{1}H-NMR signals is difficult, especially in spectral regions that are crowded with many resonances. What is needed for the NMR analysis of combinatorial libraries is a means of distinguishing between the individual sample components during spectral acquisition. Flow-through interfaces have been developed to directly couple HPLC and NMR, and this allows individual components present in a sample to be spatially resolved prior to their characterization by NMR. A second approach distinguishes between individual components of a sample solution based on differences in their diffusion rates, and does not require a separation step to be performed prior to NMR analysis.

5.2.1 Flow-through Nuclear Magnetic Resonance Interfaces

The first flow-through interfaces for liquid chromatography/nuclear magnetic resonance (LC/NMR) were developed in the late 1970s.[142,143] However, the NMR spectrometers used in these systems employed iron magnets with low field strengths, so sensitivity was severely limited (e.g. 100-μg detection limit). Developments during the early 1980s[144–146] led to the first applications of on-line LC/NMR employing superconducting magnets. Flow-through interfaces for LC/NMR consist of a hollow glass tube, through which the LC eluant flows, and an RF coil wrapped around the outside of the detection window. The design of the RF coil and related circuitry, and the internal volume and geometry of the flow cell differ by manufacturer. Diagrams of a Bruker (Karlsruhe, Germany) continuous-flow NMR probe and typical LC/NMR system configuration are shown in Figure 20.[147] The Bruker flow cell is a

Figure 20 (a) Schematic diagram of the geometry of a continuous-flow NMR probe and (b) experimental arrangement for coupling an HPLC system with an NMR spectrometer. U-shaped glass tube with a slight bulge at the detection window. An RF coil is attached to the outside of the glass tube at the bulge. The LC/NMR probe is preceded by a switching valve (see Figure 20b) that allows spectra to be collected in either continuous-flow or stopped-flow mode. The latter allows NMR experiments involving the collection of hundreds to thousands of transients to be performed without interrupting the LC separation.

In contrast to conventional NMR liquids probes, which typically spin the sample at 20 Hz to expose the sample to a uniform magnetic field, the continuous-flow probes used in LC/NMR are static. As a consequence, the NMR line widths observed in LC/NMR are 3–4 times greater than those in conventional NMR spectra. Continuous-flow LC/NMR probes produce additional line broadening when used in on-flow rather than stopped-flow mode, because the observed nuclei have limited residence times within the detection region of the probe compared with their spin–lattice and spin–spin relaxation times. Dorn reported that a sample should be resident in the detection region of a LC/NMR flow cell for a minimum of 1–6 s to minimize line broadening.[144]

The volume of sample within the region of the RF coil of a continuous-flow LC/NMR probe is only slightly smaller than the total volume of the glass cylinder containing the detection area. This high filling factor helps offset the negative effects of failing to spin the LC/NMR cell within the magnetic field. The detection limits that can be achieved with ^{1}H-NMR continuous-flow probes are dependent on the number of equivalent nuclei within the detection coil, and the spin–lattice relaxation (T_1) times of the observed protons. Albert[147] reported a detection limit of 500 ng for the benzyl CH_2 protons of *n*-butylbenzylphthalate obtained with a flow cell with a volume of 120 µL on a 600-MHz instrument. Detection under stopped-flow conditions is approximately an order of magnitude more sensitive than in on-flow mode, because of the improvements in the signal-to-noise ratio that can be achieved with long acquisition times.

Miniaturization of the basic flow-through cell design has been described for microcolumn and nanoscale separation techniques (e.g. capillary zone electrophoresis, capillary electrochromatography, and capillary HPLC).[148–150]

5.2.2 *Liquid Chromatography/Nuclear Magnetic Resonance*

LC/NMR has been applied extensively in drug metabolism studies in the pharmaceutical industry.[151–155] The relative ease with which information-rich spectra can be obtained using this technique has enabled the rapid identification of important drug metabolites in a variety of complex matrices, including blood, urine, tissue, and bile. There have been comparatively fewer applications of LC/NMR to combinatorial chemistry, presumably because commercial systems have only recently been developed for combinatorial chemistry and software for data reduction of libraries of compounds is not widely available. Chin et al.[156] reported the analysis of a mixture of four isomeric (dimethoxybenzoyl)glycines by high-performance liquid chromatography/nuclear magnetic resonance (HPLC/NMR) in 1998. The isomers were separated by reversed-phase HPLC, and NMR spectra were generated using both on-flow and stopped-flow conditions on a 500-MHz instrument. A UV chromatogram of the sample mixture is shown in Figure 21(a), and the ^{1}H-NMR spectra of the four components present are shown in Figure 21(b).

Figure 21 (a) UV trace of the chromatographic separation for a mixture of four isomeric (dimethoxybenzoyl)glycines and (b) their corresponding 500 MHz ^{1}H-NMR spectra. (Reproduced with permission from J. Chin, J.B. Fel, M. Jarosinski, M.J. Shapiro, J.R. Wareing, *J. Org. Chem.*, **63**, 386–390 (1998). Copyright 1998 American Chemical Society.)

Suppression of signals from the chromatographic eluent is a critical challenge to LC/NMR. There are a number of techniques available for eliminating interference from proton-containing solvents in LC/NMR systems. The most direct approach to eluent signal suppression involves using deuterated or halogenated solvents in the LC mobile phase. However, the high cost of deuterated solvents makes this approach impractical for conventional reversed-phase applications. Electronic pulse techniques provide the best approach to solvent signal suppression in LC/NMR. Presaturation to suppress interfering solvent signals requires lengthy saturation periods during which sample spectra cannot be acquired, which limits application of this technique to stopped-flow analysis.[157] Binomial suppression methods, such as the 1–1 hard pulse and 1331 pulse sequences[158,159] are compatible with on-flow analysis and can be used to suppress multiple solvent resonances simultaneously. Pulsed-field gradients also provide a useful means of suppressing background water signals in one-dimensional (1-D) and 2-D NMR experiments.[160–162] Developments in solvent suppression techniques for LC/NMR have been reviewed.[163]

5.2.3 Diffusion-resolved Nuclear Magnetic Resonance

Morris and Johnson[164,165] developed a 2-D NMR technique that allows ^{1}H-NMR spectra of discrete chemical species present in mixtures to be distinguished based on differences in their diffusion coefficients. 2-D NMR diffusion-ordered spectroscopy (DOSY) is performed in two steps. The first step of the DOSY experiment involves generating the 2-D NMR data using pulsed-field-gradient NMR techniques. The data are subsequently transformed and displayed with chemical shift information plotted in one dimension and diffusion coefficients in the second dimension. Transformation of NMR signal intensities versus gradient pulse areas into diffusion spectra is performed using standard computer algorithms. DOSY is potentially a powerful technique for characterizing mixtures of low-molecular-weight compounds of similar size, such as those present in combinatorial mixture libraries. A significant advantage of DOSY over LC/NMR is that spectra on individual compounds present in a mixture can be obtained directly, without requiring an initial chromatographic separation.

Extension of the standard DOSY experiment to include ^{13}C correlation information as a third dimension has been reported by Barjat et al.[166] The 3-D diffusion-ordered spectroscopy/heteronuclear multiple quantum coherence (DOSY/HMQC) spectrum of a mixture of quinine, camphene, and geraniol in methanol-d_4 is shown in Figure 22.[166] Lin et al.[167,168] combined pulsed field gradients with TOCSY in a technique they termed diffusion-encoded spectroscopy (DECODES). A limitation of DOSY is that overlapped resonances in the region between 0.5 and 2.0 ppm cannot always be resolved by diffusion alone. TOCSY, however, can resolve overlapped resonances by separating coupled spin systems in the second dimension. Hence, the DECODES technique is more effective in resolving individual components present in complex mixtures.

6 LIBRARY SCREENING BY AFFINITY SELECTION AND MASS SPECTROMETRY

Classical approaches to drug discovery involve synthesizing, purifying, characterizing and biologically screening compounds one at a time. While there have been significant advances in methods for synthesizing large numbers of compounds in combinatorial libraries, there are relatively few techniques available for screening mixtures of compounds in ways that allow detection of specific receptor–ligand interactions and preserve the native binding of these interactions. Most screening approaches use classical bioassays to test the activity of single compounds, but perform these assays in parallel to increase sample throughput (i.e. high throughput screening). Affinity-based assays, while compatible with mixtures of ligands, employ immobilized receptors or immobilized ligands and yield binding constants that may not mimic true solution-phase binding.

During the mid-1990s, a number of affinity-based screening techniques were developed to overcome the disadvantages of conventional assays. These improved strategies combine the high specificity of mass spectrometric detection with novel approaches for distinguishing receptor-bound ligands from unbound species present in combinatorial mixture libraries.

6.1 Ligand Selection by Affinity Chromatography

Affinity chromatography is a technique wherein a mixture of ligands is chromatographically separated based on their interaction with an immobilized receptor. The target receptor usually is immobilized on a solid support, and packed into a column. A solution containing the mixture library is passed through the column, and those compounds that interact strongly with the receptor are fully retained. Compounds that interact weakly with the immobilized receptor, or not at all, pass through the column unretained. The strongly retained compounds then are eluted from the affinity column using a high-ionic-strength buffer. The active mixture is passed through a desalting column to remove buffer salts, and individual components in the mixture are separated by reversed-phase HPLC prior to their characterization by ESIMS. A disadvantage of affinity chromatography as a compound selection technique is that the immobilization of receptors to the solid support may alter their binding with ligand molecules.

A variety of approaches to library screening by affinity selection and MS have been described, and they all utilize affinity separation for compound selection and ESIMS for compound identification. Nedved et al.[169] developed an automated system for screening benzodiazepine combinatorial libraries. This system consists of an immunoaffinity column containing antibodies to benzodiazepines and two reversed-phase HPLC columns coupled to a triple-quadrupole mass spectrometer through a series of electronic switching valves (see Figure 23).[169] A mixture of benzodiazepines is passed through the immunoaffinity column, where active compounds bind to the immobilized antibodies. A pH step-gradient is used to release the benzodiazepine–antibody complexes from the immunoaffinity column onto a restricted access media stationary phase that separates the active benzodiazepines from the antibody. A C-8 reversed-phase column is then used to separate the mixture of active benzodiazepines before they enter the mass spectrometer. Kelly et al.[170] adopted a more conventional approach to identify peptides that bind strongly to the Src homology 2 (SH2) domain of phosphatidylinositol 3-kinase. Active peptides eluted from a SH2 affinity column were desalted on a small molecule trap column prior to their characterization by ESIMS.

Karger et al.[171–173] developed an approach to library screening based on affinity capillary electrophoresis and mass spectrometry (ACE/MS). In affinity capillary electrophoresis (ACE), the electrophoretic mobility of a ligand in solution is altered upon complexation with a receptor molecule. Complexation with the receptor shifts the mobility of the ligand to that of the complex, and this shift in mobility corresponds to the ligand's binding affinity to the receptor. In the ACE/MS experiment, the capillary is filled with a running buffer containing the receptor. A mixture of ligands is injected into the inlet side of the capillary prior to the start of electrophoresis. Ligand molecules (both bound and free) are introduced into the electrospray source of the mass spectrometer as they migrate past the capillary exit. An advantage of ACE/MS is that the compound selection and compound identification steps of the library screening process are combined into a single step. The ACE/MS technique has been applied successfully to the screening of peptide libraries, but the technique may not be applicable to libraries of small-molecule organic compounds due to the complexities involved in developing electrophoretic separation conditions appropriate for these types of compounds.

6.2 Ligand Selection by Gel-filtration

Gel-filtration columns are packed with hydrophilic polymer beads of controlled porosity. These columns separate compounds primarily on the basis of molecular size and shape. Large molecules are excluded from the interior porous region of the beads and elute at or near the void volume of the column. Small molecules travel deep within the interior of the beads and take longer to elute from the column. The use of gel-filtration columns in library screening has focused primarily on the separation of receptor-bound ligands from combinatorial mixture libraries. Typically, a solution containing compounds from the mixture library is incubated with a solution containing the target receptor. The mixture then is passed through a gel-filtration column, where the bound ligands elute with the receptor molecules, while the unbound ligands are retained for longer. The receptor-bound ligands are liberated from the target and characterized by LC/ESIMS. A variant of this procedure has been incorporated into an automated screening methodology termed Selectronics™ and is illustrated in Figure 24.[174] In addition, this general screening procedure has been used in competitive binding experiments to identify library components with optimum binding affinity.[175]

Gel-filtration separations are best suited to ligands that have high affinity for the receptor molecule ($K_d < 1\,\mu M$).[176] Loss of ligand during the gel-filtration step is possible if the rate of dissociation of the receptor–ligand complex is fast compared with the separation time. In addition, irreversible retention of the receptor on the gel-filtration support can lead to poor ligand recoveries.

6.3 Ligand Selection by Ultrafiltration

Ultrafiltration membranes are a convenient and more robust alternative to gel-filtration columns for separating

molecules on the basis of size. Ultrafiltration membranes are manufactured of microporous cellulose triacetate or polysulfone in a variety of molecular weight cutoffs. The nominal molecular weight cutoff of an ultrafiltration membrane refers to the molecular weight of a globular protein that is 90% rejected by the membrane. Compounds with molecular weights significantly below the molecular weight cutoff pass freely through the membrane. Due to their relatively smaller surface areas, sample losses related to irreversible adsorption are rarely observed with these devices.

Van Breemen et al.[177,178] developed the technique of pulsed ultrafiltration MS by combining on-line ultrafiltration with electrospray MS. Pulsed ultrafiltration MS allows the rapid screening of combinatorial libraries for ligands that bind to receptors in solution. An outline of this technique is shown in Figure 25. The technique employs a flow-through chamber consisting of two compartments separated by an ultrafiltration membrane. During pulsed ultrafiltration, receptor-bound ligands remain in one half of the ultrafiltration chamber, while unbound compounds pass through the membrane and are washed away. Release of bound ligands is achieved by adding a small aliquot of an organic solvent to the sample compartment. The released compounds are then continuously monitored by ESIMS. The pulsed ultrafiltration chamber design allows the receptor to be reused for subsequent binding experiments, and is compatible with competitive binding studies and detection of strong-affinity ligands present at dilute concentrations in the presence of higher concentrations of weaker binders. For example, the adenosine deaminase inhibitor, erythro-9-(2-hydroxy-3-nonyl)adenine, was readily detected from a mixture of 20 adenosine analogs despite being present at a 10-fold lower concentration than the other ligands.[177]

Wieboldt et al.[179] employed ultrafiltration membranes to screen mixtures of benzodiazepines for binding affinity to antibodies raised to nitrazepam, temazepam, and oxazepam. Benzodiazepine mixtures were incubated with a specific antibody in 10 mM ammonium acetate buffer at pH 5.0, and the unbound drug ligands were separated by centrifugal filtration through a 50 000 molecular weight cutoff ultrafiltration membrane. The bound ligands were

characterized by HPLC and ESIMS, following their release from the antibody–drug complex by treatment with 1% TFA in water.

6.4 Bio-affinity Characterization Mass Spectrometry

All of the approaches to library screening described so far treat affinity selection and identification of active compounds as separate steps. As a result, these techniques have limited sensitivity due to the loss of ligand introduced by the additional sample handling required. An alternative approach developed by Smith et al.[180,181] eliminates the need for distinct separation and purification steps prior to ESIMS characterization. Bio-affinity characterization mass spectrometry (BACMS) combines ESI with Fourier transform ion cyclotron resonance (FTICR) MS in a technique that enables the direct characterization of noncovalent receptor–ligand complexes formed in solution. The basic BACMS experiment is depicted in Figure 26.[181] A solution containing the affinity receptor and ligand library is infused into the electrospray source, where the individual species and receptor–ligand complexes are transferred into the gas phase. These gas phase ions are trapped in the FTICR chamber, and the receptor–ligand complexes of interest are isolated by selected-ion accumulation. The selected-ion accumulation process is sufficiently gentle to prevent dissociation of the noncovalent complexes and allows these complexes to be observed with a good signal-to-noise ratio. This accumulation step is immediately followed by low-energy dissociation, which isolates the selected ligand molecules in the FTICR chamber. Collisionally activated dissociation then may be performed to obtain structural information on the high binding affinity ligands.

BACMS has been used to screen 256–289 member tripeptide libraries for tight binding inhibitors to carbonic anhydrase II obtained from bovine erythrocytes.[182] In this work, the relative intensities of the ions dissociated from the carbonic anhydrase II–inhibitor complexes correlate well with the binding constants of these inhibitors in solution (see Figure 27). This correlation between solution-phase and vapor-phase ordering of binding constants suggests that the data from BACMS experiments may be used to predict the order of binding affinities in solution.

Higger et al.[183] monitored the reaction between 1-chloro-2,4-dinitrobenzene (CDNB) and components of a H–γ–Glu–Cys–Xxx–OH (where Xxx is any natural amino acid except Cys, Val, Thr, and Pro) tripeptide library catalyzed by the enzyme glutathione-S-transferase (GST). Assessment of GST substrate specificity relied on detection of the products formed by reaction of the tripeptide library with CDNB, rather than on identification of tight binding ligands to the enzyme. In addition, the presence of two substrate-binding pockets on the

GST enzyme allows optimization of substrate specificity to be extended to two dimensions. Two substrate libraries each targeting one of the two binding sites on the GST enzyme would result in the formation of products representing the best binding substrates from each library.

7 COMBINATORIAL LIBRARY QUANTITATION

Classical methods for handling compounds in a traditional drug discovery environment require large quantities (0.1–1.0 g) of highly pure material. Product yields from organic synthesis usually are calculated based on the mass of purified product obtained. Accurate measurement of pharmacological activity requires that known concentrations of test compounds be prepared by dissolving an accurately weighed amount of compound in an accurately measured volume of solvent. Product yields from combinatorial library synthesis often are too low (1–10 mg) to permit accurate weighing. In addition, split-synthesis techniques produce mixtures that are difficult to quantitate on a per-compound basis. Consequently, there has been considerable interest in developing reliable methods for determining the reaction yields and solution concentrations of combinatorial samples that do not require individual compounds to be accurately weighed.

The combination of HPLC and UV detection provides a rapid, reproducible, and sensitive means of quantifying compounds in solution. Accurate quantitation by UV, however, requires the use of well-characterized reference standards due to the wide variability in the molar absorptivity of organic compounds, and this has presented a serious impediment to the quantitation of combinatorial samples. Accurate quantitation of combinatorial samples requires a detector whose response depends only on the amount (concentration) of compound present in solution and provides a signal that is independent of molecular structure. Three detectors have emerged that are compatible with the requirements of HPLC and provide the degree of ''universal'' response required for accurate quantitation of combinatorial samples.

7.1 Quantitation using ^{1}H-Nuclear Magnetic Resonance Spectroscopy

Sample quantitation by ^{1}H-NMR is superior to quantitation by UV detection, because the integral intensity of a given resonance band in a ^{1}H-NMR spectrum is directly proportional to the number of proton nuclei contributing to that signal. Optimizing the instrument parameters to minimize quantitation errors, however, requires an understanding of the processes involved in acquiring a spectrum. During an NMR experiment, the bulk magnetization of protons in the analyte molecule is perturbed through application of an RF pulse. After a short delay, the exponential free induction decay (FID) signal produced as the system returns to equilibrium is digitized, averaged, and transformed to yield a frequency domain spectrum. The exponential decay of the FID signal is a function of the spin–spin (T_2) relaxation time, while return of the perturbed spin system to equilibrium is governed by the spin–lattice (T_1) relaxation time. In other words, the acquisition time in an NMR experiment depends on T_2, while the pulse repetition rate depends on T_1. The value of T_1 usually is greater than T_2 for organic molecules with a molecular weight less than 1000 Dal.

A significant problem in obtaining accurate quantitation in ^{1}H-NMR is related to variable spin–lattice relaxation times among protons in the sample molecule. Quantitation errors arise when the RF pulse rate is faster than T_1 for any of the sample nuclei. The situation becomes more complex when sample quantitation is performed using flow-through NMR systems. The effective T_1 and T_2 values of a proton in a flow-through system are related to their static values and the residence time of the molecule in the NMR detector coil. As a consequence, quantitative NMR experiments should be designed such that the RF pulse rate is five times the value of T_1 for the proton with the longest spin–lattice relaxation time, and the sample is resident within the region of the NMR detector coil for 1–6 s during measurement.[184] A number of additional experimental factors that can lead to spectral distortions in NMR and interfere with sample quantitation have been described.[185,186]

Quantitation by ^{1}H-NMR spectroscopy involves measuring the integral intensity of a specific sample resonance band relative to that of a resonance band corresponding to an internal standard. The major requirements placed on the choice of internal standard are: the proton resonances of the internal standard should not overlap the resonances from the sample; the internal standard must be chemically compatible with the sample; and the nuclei in the internal standard should have short T_1 relaxation times. Hexamethyldisiloxane is a useful internal standard for ^{1}H-NMR, because of its small chemical shift (0.07 ppm) relative to tetramethylsilane. In a conventional quantitation experiment, the sample and internal standard are combined in a standard NMR sample tube, and a ^{1}H-NMR spectrum recorded in the usual manner. The concentration of sample in solution is calculated as shown in Equation (1):

$$M_a = \frac{I_a}{n_a}\frac{n_s M_s}{I_s} \quad (1)$$

where n represents the number of protons assigned to the resonance signal, M is the molar concentration, and I is the integrated intensity of the internal standard (s) and analyte (a). This method will lead to erroneous quantification results if the sample contains impurities with ^{1}H-NMR resonances that overlap the signals corresponding to the compound of interest. Accurate quantitation of mixtures is achieved by performing a chromatographic separation prior to ^{1}H-NMR analysis.

The requirements for sample quantitation in continuous-flow HPLC/NMR experiments have been elaborated by Godejohann et al.[187] There are two methods for incorporating an internal standard in an HPLC/NMR experiment: direct addition of the internal standard to the HPLC mobile phase; and injection of a fixed amount of internal standard following sample injection. The former technique is employed in gradient HPLC to compensate for the influence of varying eluent composition on the intensity of resonance bands in the NMR spectrum. Injection of a fixed volume of the internal standard following sample injection is compatible with isocratic HPLC separations.

The technique of sample quantitation by ^{1}H-NMR with internal standard has been applied successfully to the determination of the potency of active ingredients in pharmaceutical dosage forms[188] and the yield of products originating from the SPS of combinatorial libraries.[189] A representative ^{1}H-NMR spectrum of a product from a combinatorial library in the presence of internal standard is shown in Figure 28.

Figure 28 Quantitation of the direct cleavage product from a SPOS combinatorial library by ^{1}H-NMR with internal standard. (Reproduced with permission from B.C. Hamper, S.A. Kolodziej, A.M. Scates, R.G. Smith, E. Cortez, *J. Org. Chem.*, **63**, 708–718 (1998). Copyright 1998 American Chemical Society.)

7.2 Quantitation using Chemiluminescent Nitrogen Detection

Chemiluminescent nitrogen detection (CLND) instruments respond only to nitrogen present in organic compounds. Sample detection by CLND involves oxidizing the sample at approximately 1000 °C to convert nitrogen in the compound to nitric oxide. The nitric oxide is reacted with ozone to produce nitrogen dioxide in an excited state, which releases a photon as it returns to the ground electronic state. The emitted photons are detected using a photomultiplier tube, whose output is amplified to yield an analog signal. In contrast to UV detectors, the response of a chemiluminescent nitrogen detector is linearly related to the total mass of compound present in the sample and is independent of concentration.

The first practical application of CLND coupled with HPLC was reported by Fujinari et al.[190] for the analysis of ammonium nitrogen in wastewater. The combination of reversed-phase HPLC and CLND has been applied successfully to the purity assessment of synthetic peptides obtained by SPPS.[191] This combination of a high resolution separation technique and ''universal'' detection also has been utilized to assess product yields and purities of nonpeptide combinatorial libraries.[192,193] A series of chromatograms comparing the response of an equimolar mixture of nitrogen-containing organic compounds separated by gradient reversed-phase HPLC with UV detection at 214 nm and 270 nm and CLND is shown in Figure 29.

CLND has been reported to yield similar response to nitrogen-containing, small-molecule organic compounds over a linear range of 25 to 6400 pmol of nitrogen.[193] Furthermore, quantitation by CLND results in an error of approximately 10% over a wide range of compound classes. The use of CLND as a detector in reversed-phase HPLC imposes practical limitations on the choice of mobile phase eluents and buffers. Mobile phase components must be nitrogen-free, hence organic alcohols (e.g. methanol) are frequently used in place of acetonitrile as mobile phase modifiers.

7.3 Quantitation using Evaporative Light Scattering Detection

Like CLND, evaporative light scattering (ELS) detectors respond to the total mass of compound injected, rather than yielding a concentration-dependent response. The principle of operation of an ELS detector is based on measurement of the intensity of light scattered by the analyte following evaporation of the carrier solvent (e.g. the HPLC mobile phase). The HPLC column effluent enters the detector through a narrow bore tube where it is mixed with a high-velocity stream of nitrogen gas and passed through a nebulizer. The nebulized sample stream enters a heated tube, maintained at a sufficient temperature to cause rapid evaporation of the carrier solvent. The stream of solid analyte particles that is produced passes a detection system consisting of a source and photodiode detector placed 90° apart and perpendicular to the central axis of the drift tube. As the analyte passes through the detection region, the solid particles scatter light through a combination of Mie-scattering, reflection and refraction.[194,195] The intensity of the scattered light is measured by the photodiode and amplified to produce an analog signal proportional to the

Figure 29 Chromatograms of a mixture of 'drug-like' compounds separated by reversed-phase HPLC with gradient elution and detected by UV at 214 nm and 270 nm and by CLND. The injected sample contained 2 nmol each of (1) caffeine, (2) triprolidine, (3) chlorpheniramine, (4) diphenylalanine, (5) 6-nor-6-allylsergic acid diethylamide, (6) angiotensin II, (7) diphenhydramine, (8) doxepin, and (9) dibucaine. amount of analyte present in the injected sample. ELS detectors exhibit a sigmoidal response to compounds, but, the detector's response can be made linear over a range of 2–3 orders of magnitude by plotting intensity versus mass on a log/log scale. The ELS detector's nonlinear response is attributed to the physics of Mie-scattering. The Mie-scattering efficiency of particles is maximal over a narrow range of particle diameters. Small radius particles generated at low analyte concentrations scatter less efficiently, while at high analyte concentrations changes in the surface-to-volume ratio of larger radius particles leads to less efficient light-scattering.

When combined with HPLC instruments, ELS detectors are highly effective at providing on-line quantitation of small organic compounds derived from combinatorial libraries.[196] Reliable quantitation requires that a well-characterized standard belonging to the same class of compounds present in the combinatorial library be used to calibrate the detector. The pair of chromatograms shown in Figure 30 illustrate the more "universal" response of ELS detection compared with conventional UV detection towards compounds of similar structural class (e.g. steroids). The response of the ELS detector depends on the ability of the nebulizer to produce analyte particles of the optimal size (0.8 μm) for effective Mie-scattering. This process is dependent on a variety of factors including solvent vaporization enthalpy, nebulizer gas flow rate, solvent composition, analyte molecular weight, and analyte polarity. The best results are obtained with HPLC separations performed under normal-phase conditions with solutes of a mass greater than 150–200 Dal.

ABBREVIATIONS AND ACRONYMS

ACE	Affinity Capillary Electrophoresis
ACE/MS	Affinity Capillary Electrophoresis and Mass Spectrometry
APCI	Atmospheric Pressure Chemical Ionization
APCIMS	Atmospheric Pressure Chemical Ionization Mass Spectrometry
ATR	Attenuated Total Reflectance
BACMS	Bio-affinity Characterization Mass Spectrometry
Boc	*t*-Butoxycarbonyl
CDNB	1-Chloro-2,4-Dinitrobenzene
CID	Collision-induced Dissociation
CIRCLE	Cylindrical Internal Reflectance
CLND	Chemiluminescent Nitrogen Detection
COSY	Correlation Spectroscopy
DECODES	Diffusion-encoded Spectroscopy
DMSO	Dimethyl Sulfoxide
DOSY	Diffusion-ordered Spectroscopy
DOSY/HMQC	Diffusion-ordered Spectroscopy/ Heteronuclear Multiple Quantum Coherence
DRIFT	Diffuse Reflectance Infrared Fourier Transform
ECD	Electron Capture Detection
ELS	Evaporative Light Scattering
ESI	Electrospray Ionization
ESIMS	Electrospray Ionization Mass Spectrometry
FIA/MS	Flow Injection Analysis Mass Spectrometry
FID	Free Induction Decay
Fmoc	9-Fluorenylmethyloxycarbonyl
FTICR	Fourier Transform Ion Cyclotron Resonance
FTIR	Fourier Transform Infrared

FTRS	Fourier Transform Raman Spectroscopy
GC	Gas Chromatography
GST	Glutathione-S-transferase
HMQC	Heteronuclear Multiple Quantum Coherence
HPLC	High-performance Liquid Chromatography
HPLC/DRIFT	High-performance Liquid Chromatography/Diffuse Reflectance Infrared Fourier Transform
HPLC/FTIR	High-performance Liquid Chromatography/Fourier Transform Infrared
HPLC/NMR	High-performance Liquid Chromatography/Nuclear Magnetic Resonance
IR	Infrared
LC	Liquid Chromatography
LC/ESI	Liquid Chromatography/ Electrospray Ionization
LC/ESIMS	Liquid Chromatography Coupled with Electrospray Ionization Mass Spectrometry
LC/MS	Liquid Chromatography/Mass Spectrometry
LC/NMR	Liquid Chromatography/Nuclear Magnetic Resonance
MAGIC/HPLC/ FTIR	Mono-disperse Aerosol Generation Interface for Combining High-performance Liquid Chromatography with Fourier Transform Infrared
MALDI	Matrix-assisted Laser Desorption/ Ionization
MALDI/FTMS	Matrix-assisted Laser Desorption/ Ionization Fourier Transform Mass Spectrometry
MALDI/TOFMS	Matrix-assisted Laser Desorption/ Ionization Time-of-flight Mass Spectrometry
MAS	Magic-angle Spinning
MCT	Mercury–Cadmium–Telluride
MS	Mass Spectrometry
MS/MS	Tandem Mass Spectrometry
NMR	Nuclear Magnetic Resonance
NOE	Nuclear Overhauser Effect
PAFTIR	Photoacoustic Fourier Transform Infrared
PCR	Polymerase Chain Reaction
RF	Radiofrequency
SBFTIRM	Single-bead Fourier Transform Infrared Microspectroscopy
SECSY	Spin-echo Correlated Spectroscopy
SH2	Src homology 2
SPOS	Solid-phase Organic Synthesis
SPPS	Solid-phase Peptide Synthesis
SPS	Solid-phase Synthesis
TFA	Trifluoroacetic Acid
THF	Tetrahydrofuran
TLC	Thin-layer Chromatography
TOCSY	Total Correlation Spectroscopy
TOF	Time-of-flight
TOF/SIMS	Time-of-flight Secondary Ion Mass Spectrometry
UV	Ultraviolet
1-D	One-dimensional
2-D	Two-dimensional
3-D	Three-dimensional
